Purpose: Our recent study showed a high rate of HBsAg clearance in inactive HBsAg carriers (IHCs) treated with pegylated IFN (PEG-IFN). To better understand the immune-mediated component of HBsAg clearance, this study investigated the role of serum immunoglobulin G (IgG) and its subclasses in predicting HBsAg clearance in IHCs with PEG-IFN therapy.

Methods: In this study, IHCs received PEG-IFN for 96 weeks. Subjects who achieved clearance of HBsAg were considered responders (R group), and those in whom HBsAg was not cleared were considered non-responders (NR group). The HBsAg, ALT, and serum IgG subtypes (IgG1, IgG2, IgG3, IgG4) were tested at baseline, and at 12 and 24 weeks of treatment. To evaluate the factors in predicting HBsAg clearance, univariate and multivariate logistic regression analyses were performed. The receiver operator characteristic curves and the area under the receiver operator characteristic curve (AUROC) were used to evaluate prognostic values.

Results: Our results showed that 39 cases obtained HBsAg clearance (group R), while 21 cases did not (group NR). There was no significant difference in age, ALT, and AST levels between the two groups. The serum levels of IgG1, IgG2, IgG3 and IgG4 at baseline, and at 12 and 24 weeks were significantly lower in IHC with HBsAg clearance than in the NR group. Univariate logistic regression analysis showed that serum IgG1, IgG2, IgG3, and IgG4 levels at baseline, and at 12, and 24 weeks were all strong predictors of HBsAg clearance. In all indicators, IgG2 had the highest AUROC at baseline and IgG3 the highest AUROC at week 12. A multifactor logistic analysis was performed with $y=33.933-0.001\times\text{BaselineIgG1}-0.002\times\text{BaselineIgG2}$. The area under the curve was 0.941 with 100% sensitivity and 76.19% specificity.
INTRODUCTION

Chronic hepatitis B virus (HBV) infection is a major public health problem in China with approximately 70 million cases (1). Hepatitis B surface antigen (HBsAg) clearance, although a desirable therapeutic goal, is extremely difficult to obtain clinically. Research into the mechanism of HBsAg clearance is severely hampered by the lack of specimens from HBsAg-cleared patients. According to recent reports, Inactive surface antigen carriers (IHCs) are a large population that accounts for approximately 36% of patients with HBV infection (2) and amount to 30 million individuals in total (3). IHCs are defined by normal alanine aminotransferase (ALT), HBV DNA ≤2000 IU/mL, and hepatitis B e antigen (HBeAg)-negative status. Our and other recent studies have shown that IHC treated with pegylated-interferon (PEG-IFN) results in high HBsAg clearance, with HBsAg clearance rates of 44.7% to 65% (4–6). In addition to cellular immunity, humoral immunity also plays an important role in HBV infection and elimination. Immunoglobulin G (IgG) is the main component of serum immunoglobulins and is classified into four isoforms, IgG1, IgG2, IgG3, and IgG4, depending on the amino acid composition and structure of the hinge region (7). Serum IgG and subclasses play a central role in the humoral immune response. IgG1 is the most abundant IgG subclass in the human serum, followed by IgG2, IgG3, and IgG4. IgG1 mediates the immune response to pathogens, binding to soluble and membrane protein antigens through its variable region, while activating the effector mechanisms of the innate immune system, binding to C1q to cause complement-dependent cytotoxicity and binding to each of the different Fc receptors to cause antibody-dependent cell-mediated cytotoxicity (8). IgG3 appears early in the infection and may limit the excessive inflammatory response (9). IgG4 usually appears in a non-infected setting or after prolonged and repeated exposure to antigens and is associated with IgG4-related diseases, involving multiple organs and tissues in chronic progressive autoimmune disorders (10), which were patients excluded from this study. Recent studies have reported that IgG may be involved in the onset and development of HBV infection, that the severity of HBV pathogenesis is related to immune function of the body, and that serum IgG levels are significantly higher in patients with chronic liver failure and severe chronic hepatitis B than in patients with mild to moderate disease and are positively correlated with the severity of the disease (11, 12).

However, the role of IgG in antiviral therapy, particularly in HBsAg clearance, has not been reported. IHCs were recruited in this study and were treated with PEG-IFN for 96 weeks. We detected the levels of serum IgG and its subtypes during treatment and investigated their value in predicting the clearance of HBsAg.

MATERIALS AND METHODS

Patients

A total of 60 IHCs were recruited for the study and received regular follow-up visits at Beijing Youan Hospital, Capital Medical University. Five healthy students were recruited as healthy controls.

All IHCs met the criteria defined in the prevention and treatment guidelines for chronic hepatitis B (2019 edition) (1): (i) HBsAg positive >6 months and HBsAg <1000 IU/mL, HBeAg negative, anti-HBe positive/positive; (ii) HBV DNA <2000 IU/mL, ALT normal (male<50 IU/L, female<40 IU/L); (iii) white blood cell count >4×10⁹/L, platelet count >150×10⁹/L; (iv) total bilirubin <34 µmol/L, albumin >40 g/L. Exclusion criteria: (i) history of autoimmune diseases; (ii) Human immuno-deficiency virus or Hepatitis C Virus or Hepatitis E Virus coinfection; (iii) Pregnant, lactating women and those who are preparing to have children soon; (iv) liver cirrhosis or liver cancer; (v) history of severe heart disease, including unstable or uncontrolled heart disease within 6 months; (vi) history of mental illness or psychiatric disorders. (vii) Uncontrolled epilepsy; (viii) Unabated alcohol or drug abuser. (ix) Uncontrolled diabetes mellitus, hypertension, thyroid disease, retinopathy; (x) contraindication to interferon. All healthy controls were HBsAg-negative and anti-HBs -positive.

Treatment and Efficacy

The 60 patients enrolled in the study were treated with PEG-IFN 135 µg weekly by subcutaneous injection. Treatment was stopped if neutrophil counts were <0.50×10⁹ or platelet count was <25×10⁹, or a serious adverse events occurred. The total duration of treatment was 96 weeks. The effect of the treatment was determined by HBsAg clearance. Subjects who achieved HBsAg clearance in 96 weeks were considered responders (group R), and those in whom HBsAg was not cleared were considered non-responders (group NR).

Abbreviations: HBV, hepatitis B virus; HBsAg, hepatitis B surface antigen; IHCs, Inactive surface antigen carriers; ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; PEG-IFN, pegylated-interferon; IgG, immunoglobulin G; SD, standard deviation; ROC, Receiver operator characteristic; AUROC, area under the ROC curve.
**Ethics Approval**

The protocol and the consent form for the study were approved by the research ethics committee of the Beijing You’an Hospital, Capital Medical University, China ([2017]24).

**Laboratory Tests**

Blood samples were collected at baseline, and after 12, and 24 weeks of treatment and were tested for HBV DNA, HBsAg levels, liver function, and routine blood tests. Serum levels of the IgG subtypes (IgG1, IgG2, IgG3, IgG4) were also measured simultaneously. HBV DNA was quantified using the fluorescence quantitative (FQ)-PCR, Cobas Taqman real-time polymerase chain reaction 2.0 system (Roche, Germany), with a lower limit of detection of 20 IU/mL. HBsAg quantification was performed using the HBsAg quantification kit from Roche, having a lower limit of detection of 0.05 IU/mL. Liver function testing was performed by reagents from Shanghai Kehua Dongling Company (China). IgG subtypes were detected by enzyme-linked immunosorbent assay kits from Jianglai Biologicals (China). In order to measure the concentration of IgG subtypes in the sample, this IgG ELISA Kit includes a set of calibration standards. The calibration standards are assayed at the same time as the samples and allow the operator to produce a standard curve of Optical Density versus IgG subtypes concentration. The concentration of IgG subtypes in the samples is then determined by comparing the O.D. of the samples to the standard curve.

**Statistical Analysis**

Data analysis was performed using SPSS 25 software (IBM SPSS, Chicago, IL, USA), and values were expressed as mean ± standard deviation (SD) and median (25th, 75th). The Mann–Whitney U test or Student’s t-test was applied for quantitative variables, and the chi-square or Fisher’s exact test was used for categorical variables. Receiver operator characteristic (ROC) curves, which plot sensitivity by 1 – specificity, and the area under the ROC curve (AUROC) were used to evaluate the prognostic values of the quantitative HBsAg, ALT, IgG1, IgG2, IgG3, IgG4 at baseline, and at weeks 12 and 24 as well as the HBsAg change form baseline at weeks 12 and 24 to predict HBsAg clearance. Univariate and multivariate logistic regression analyses were performed to evaluate the magnitude and significance of the association. A two-sided P-value <0.05 was considered statistically significant.

**RESULTS**

**Levels of Serum IgG1, IgG2, IgG3, and IgG4 in IHCs and Healthy Subjects**

Sixty IHCs (43 males and 17 females with a mean age of 38.95 ± 11.23 years) and five healthy controls with a mean age of 27.60 ± 1.67 years were enrolled. IgG1, IgG2, IgG3, and IgG4 levels were 13328.17 μg/mL, 6186.79 μg/mL, 2024.53 μg/mL, and 660.76 μg/mL in IHCs and 9144.00 μg/mL, 4342.61 μg/mL, 1772.73 μg/mL, 395.17 μg/mL, respectively in healthy controls. The levels of IgG1, IgG2, IgG3, and IgG4 were significantly higher in IHC patients than in healthy controls. (p<0.001, p=0.003, p=0.079, p<0.001, respectively) (Figure 1).

**The Level of IgG Subtype at Baseline and During Treatment in R and NR Group**

A total of 60 patients enrolled in the study were treated with PEG-IFN for 96 weeks. Of these, 39 cases achieved HBsAg clearance (group R) and 21 cases did not (group NR). There was no statistical difference in age, or in ALT and AST values between the two groups. HBsAg quantification at baseline, at 12 and 24 weeks were all lower in the R group than in the NR group (P=0.067, P=0.001, P<0.001). In addition, the levels of serum immunoglobulin IgG1, IgG2, IgG3, and IgG4 at baseline, 12 and 24 weeks were all significantly lower in patients with HBsAg clearance than in the NR group (Table 1 and Figure 1).

**HBsAg Changes in IHC Patients After PEG-IFN Treatment**

The baseline HBsAg quantification in group R was not significantly different from group NR. After PEG-IFN treatment, HBsAg showed a significant downward trend, with HBsAg quantification at 12 and 24 weeks significantly lower than baseline, especially in patients in group R. HBsAg quantification at 12 and 24 weeks was significantly lower in group R than in group NR (P=0.001, P<0.001) (Figure 2).

**The Value of Serum IgG on HBsAg Clearance**

To evaluate factors at identifiable at baseline or in early treatment able to predict HBsAg clearance, univariate logistic regression analysis was conducted. The variables included in the analysis were HBsAg, ALT, IgG1, IgG2, IgG3, and IgG4 at baseline, 12, and 24 weeks as well as HBsAg change form baseline at weeks 12 and 24. The results showed that the serum levels of IgG1, IgG2, IgG3, and IgG4 at baseline, 12, and 24 weeks were all strong predictors of HBsAg clearance as well as HBsAg levels at 12 and 24 weeks, HBsAg changes from baseline and at 12 and 24 weeks. Sex, age, baseline HBsAg and ALT levels were not statistically significant (Table 2).

**Value of Baseline Variables for Predicting HBsAg Clearance**

In the univariate analysis, the P-values for baseline HBsAg, IgG1, IgG2, IgG3, and IgG4 were all less than 0.1; the respective ROC curves for predicting HBsAg clearance are shown in Figure 4. The results suggest that baseline IgG2 values had the largest area under the curve (AUROC 0.880), followed by the baseline levels of IgG1 (AUROC 0.824), IgG3 (AUROC 0.771), HBsAg (AUROC 0.646), and IgG4 (AUROC 0.596). The areas under the ROC curves were further compared and the...
predictive value of baseline IgG2 was significantly higher than baseline HBsAg (Figure 3 and Table 3).

**Value of Variables at 12 Weeks of PEG-IFN Treatment for Predicting HBsAg Clearance**

Changes in week 12 IgG1, IgG2, IgG3, IgG4, HBsAg, and HBsAg levels from baseline were all strong predictors of HBsAg clearance. The largest AUC was the week 12 IgG3 (AUROC 0.867), followed by week 12 IgG1 (AUROC 0.852), week 12 IgG2 (AUROC 0.827), which were all better than week 12 HBsAg (AUROC 0.733) and HBsAg change form baseline (AUROC 0.711) (Figure 4 and Table 3).

**Value of Variables at 24 Weeks of PEG-IFN Treatment for Predicting HBsAg Clearance**

The AUROC for the week 24 HBsAg levels (AUROC 0.804), week 24 IgG1 (AUROC 0.784), and week 24 IgG3 (AUROC 0.780) levels (Figure 5). Further comparison of the AUROC indicated that even though the curves for HBsAg and HBsAg showed the changes from baseline were higher than the IgG1, IgG2, IgG3, and IgG4, but were not statistically different (Table 3).

**Multivariate Logistic Regression Analysis for Predicting HBsAg Clearance**

According to the univariate regression analysis, strong predictors included: baseline IgG1, IgG2, IgG3, and IgG4 levels; week 12 IgG1, IgG2, IgG3, and IgG4 levels; and week 24 IgG1, IgG2, IgG3, and IgG4 levels; HBsAg at 12 and 24 weeks, HBsAg changes from baseline at 12 and 24 weeks. A multi-factor logistic analysis was performed with y=33.933-0.001*Baseline IgG1-0.002*Baseline IgG2. The AUROC was up to 0.941 with 100% sensitivity and 76.19% specificity. The optimal cutoff points of Baseline IgG1 was <15100ug/mL and Baseline IgG2 was <6750.67ug/mL respectively. (Figure 6).
| Parameter | R group n=39 | NR group n=21 | P-value |

DISCUSSION

The immunological mechanisms underlying HBV infection, particularly HBsAg clearance, are currently unclear. In this study, a cohort of IHCs treated with interferon was established, high HBsAg clearance rates were obtained, and blood specimens were dynamically retained, which provided the necessary basis for further work on mechanisms related to HBsAg clearance.

FIGURE 2 | HBsAg at baseline, and at 12 and 24 weeks of PEG-IFN treatment in the R and NR groups. (A) The level of HBsAg in the R group was lower than in the NR group, but were not significantly different (P=0.067). The levels of HBsAg in the R group was significantly lower than in the NR group (P=0.001, P<0.001) at 12 and 24 weeks of treatment. (B) HBsAg showed a significant downward trend after PEG-IFN treatment in IHCs, with HBsAg quantification at 12 and 24 weeks significantly lower than baseline, especially in the R group.

TABLE 2 | Variables at baseline and early treatment associated with HBsAg clearance (univariable analysis).

| Variable | OR | 95% CI | P-value |
|----------|----|--------|---------|
| Sex | 0.32 | (0.423, 4.783) | 0.569 |
| Age | 0.72 | (0.934, 1.027) | 0.397 |
| Baseline HBsAg | 3.17 | (0.247, 1.070) | 0.075 |
| Baseline ALT | 0.82 | (0.987, 1.005) | 0.366 |
| Baseline IgG1 | 13.80 | (0.999, 1.000) | <0.001 |
| Baseline IgG2 | 13.98 | (0.997, 0.999) | <0.001 |
| Baseline IgG3 | 11.37 | (0.994, 0.998) | 0.001 |
| Baseline IgG4 | 4.44 | (0.990, 1.000) | 0.035 |
| Week 12 HBsAg | 8.15 | (0.215, 0.752) | 0.004 |
| Week 12 HBsAg change from baseline | 5.47 | (1.237, 11.234) | 0.019 |
| Week 12 ALT | 0.59 | (0.995, 1.012) | 0.442 |
| Week 12 IgG1 | 13.61 | (0.999, 1.000) | <0.001 |
| Week 12 IgG2 | 13.22 | (0.998, 0.999) | <0.001 |
| Week 12 IgG3 | 15.16 | (0.992, 0.997) | <0.001 |
| Week 12 IgG4 | 7.46 | (0.986, 0.998) | 0.006 |
| Week 24 HBsAg | 9.74 | (0.175, 0.671) | 0.002 |
| Week 24 HBsAg change from baseline | 10.72 | (1.772, 9.764) | 0.001 |
| Week 24 ALT | 0.986 | (0.989, 1.012) | 0.982 |
| Week 24 IgG1 | 7.68 | (0.999, 1.000) | 0.006 |
| Week 24 IgG2 | 11.67 | (0.998, 1.000) | 0.001 |
| Week 24 IgG3 | 8.81 | (0.993, 0.999) | 0.003 |
| Week24 IgG4 | 10.84 | (0.980, 0.995) | 0.001 |
Persistent HBV infection can lead to impaired immune function in the body, and in addition to a decrease in the number and function of specific T cells, the humoral immune response is severely reduced. Previous studies have analyzed the relationship between the level of immunoglobulins in patients with chronic hepatitis B infection and the activity and severity of the disease and found that IgG levels are positively correlated with the severity of the disease (11, 12). After treatment with nucleoside analogs, HBV DNA levels decreased, and serum immunoglobulin level decreased accordingly (13, 14). However, it has not been reported how the immunoglobulin levels change after interferon treatment, particularly in HBsAg clearance patients. In this study, we investigated the changes of IgG and its subtypes in IHCs treated with interferon and analyzed their correlation with HBsAg clearance.

**TABLE 3 |** Comparison of the areas under the ROC curves for each indicator at baseline and 12 weeks, 24 weeks.

| Indicator of baseline | Difference between areas | 95% CI       | P   |
|-----------------------|--------------------------|--------------|-----|
| Baseline IgG1 vs. Baseline HBsAg | 0.18 | -0.026, -0.381 | 0.09 |
| Baseline IgG2 vs. Baseline HBsAg | 0.23 | 0.053, -0.414 | 0.01 |
| Baseline IgG3 vs. Baseline HBsAg | 0.12 | -0.067, -0.315 | 0.20 |
| Baseline IgG4 vs. Baseline HBsAg | 0.05 | -0.179, -0.279 | 0.67 |
| Week 12 IgG1 vs. Week 12 HBsAg change from baseline | 0.14 | -0.029, -0.311 | 0.10 |
| Week 12 IgG2 vs. Week 12 HBsAg change from baseline | 0.18 | -0.082, -0.315 | 0.25 |
| Week 12 IgG3 vs. Week 12 HBsAg change from baseline | 0.16 | 0.003, -0.310 | 0.04 |
| Week 12 IgG4 vs. Week 12 HBsAg change from baseline | 0.02 | -0.164, -0.211 | 0.80 |
| Week 12 IgG1 vs. Week 12 HBsAg | 0.12 | -0.068, -0.305 | 0.21 |
| Week 12 IgG2 vs. Week 12 HBsAg | 0.10 | -0.100, -0.289 | 0.34 |
| Week 12 IgG3 vs. Week 12 HBsAg | 0.13 | -0.027, -0.295 | 0.10 |
| Week 12 IgG4 vs. Week 12 HBsAg | 0.05 | -0.138, -0.229 | 0.62 |
| Week 24 IgG1 vs. Week 24 HBsAg change from baseline | 0.04 | -0.161, -0.233 | 0.72 |
| Week 24 IgG2 vs. Week 24 HBsAg change from baseline | 0.05 | -0.168, -0.258 | 0.68 |
| Week 24 IgG3 vs. Week 24 HBsAg change from baseline | 0.03 | -0.135, -0.199 | 0.71 |
| Week 24 IgG4 vs. Week 24 HBsAg change from baseline | 0.02 | -0.177, -0.223 | 0.82 |
| Week 24 IgG1 vs. Week 24 HBsAg | 0.01 | -0.194, -0.215 | 0.92 |
| Week 24 IgG2 vs. Week 24 HBsAg | 0.02 | -0.199, -0.238 | 0.86 |
| Week 24 IgG3 vs. Week 24 HBsAg | 0.01 | -0.165, -0.178 | 0.94 |
| Week 24 IgG4 vs. Week 24 HBsAg | 0.01 | -0.208, -0.210 | 0.98 |
Several studies have confirmed that IHCs receiving IFN-based antiviral therapy can achieve higher HBsAg clearance rates. In this study, 60 IHCs were treated with IFN for 96 weeks, of which 39 patients achieved HBsAg clearance. During treatment, ALT and AST in the NR and R groups were increased, especially in HBsAg clearance group, which was similar to previous reports, suggesting that patients with good response to interferon therapy often experienced elevated ALT (15, 16). After treatment with PEG-IFN, the quantity of HBsAg at 12 weeks and 24 weeks was significantly lower than baseline, especially in the R group, suggesting that patients with rapidly declining HBsAg in the treatment had a higher incidence of HBsAg clearance (17). Therefore, many studies have indicated that changes in ALT and HBsAg at baseline and during treatment were good predictors of HBsAg clearance (15, 18, 19).

In this study, serum IgG1, IgG2, IgG3, and IgG4 levels were measured at baseline, and at 12 weeks, and 24 weeks of PEG-IFN treatment in IHCs. The levels of IgG1, IgG2, IgG3, and IgG4 were significantly lower in patients with HBsAg clearance than in non-cleared patients at all timepoints. Furthermore, we found the AUROC curves of serum IgG were significantly higher in patients with HBsAg clearance with an AUROC of up to 0.941, a sensitivity of 100%, and a specificity of 76.19%.

This study provides evidence supporting serum IgG, as a clinical predictor of HBsAg clearance, which has a higher predictive value compared to the conventional predictors HBsAg and ALT levels. However, this study is a single-center exploratory study with a relatively small number of patients, and the exact predictive efficacy needs to be further validated in a larger sample size.
