Understanding the interplay between spin and heat is a fundamental and intriguing subject. Here we report thermal spin injection and accumulation in CoFe/MgO/n-type Ge contacts with an asymmetry of tunnel spin polarization. Using local heating of electrodes by laser beam or electrical current, the thermally-induced spin accumulation is observed for both polarities of the temperature gradient across the tunnel contact. We observe that the magnitude of thermally injected spin signal scales linearly with the power of local heating of electrodes, and its sign is reversed as we invert the temperature gradient. A large Hanle magnetothermopower (HMTP) of about 7.0% and the Seebeck spin tunneling coefficient of larger than 0.74 meV K⁻¹ are obtained at room temperature.

The tremendous power consumption and accompanying heat generation in current electronic devices requires alternative technologies to provide a solution for the energy issues and to realize the energy efficient electronics. Spintronics is a viable route for it, using the spin degree of freedom in addition to the conventional charge transport. Recently another important ingredient, namely heat, appears on the stage. It has been reported that the temperature gradient and heat flow in ferromagnetic structures gives rise to a variety of spin related phenomena. Understanding the interplay between heat and spin transport is a fundamental and intriguing subject but also offers unique possibilities for emerging electronics based on the combination of thermoelectrics and spintronics.

Especially in SC-based spintronics, the functional use of heat provides a new route to inject and control of spin in semiconductors (SCs). The generation of non-equilibrium spin populations (i.e. spin accumulation) in non-magnetic SC is a central issue of SC-based spintronics. Significant progress has been made on the spin accumulation in various SC systems by means of circularly polarized light, spin-polarized tunneling, hot-electron spin filtering, spin-orbit interaction, or magnetization dynamics.

Intriguingly, Le Breton et al. have reported a rather different mechanism for the spin accumulation, in which temperature difference across a ferromagnet (FM)/oxide/SC tunnel contact can induce the spin accumulation in SC via Seebeck spin tunneling (SST). It was found that the SST effect, involving thermal transfer of spin angular momentum from FM to SC without a tunneling charge current, is a purely interface-related phenomenon of the tunnel contact and governed by the energy dependence of its tunnel spin polarization. This provides a conceptually new mechanism for the generation of Δµ in SC as well as for the functional use of heat in spintronic devices. The SST and thermal spin accumulation (Δµth) in p-type SC (e.g., p-type Si) have been intensely studied using a Ni₈₀Fe₂₀/AlₓO₃/SiO₂/p-SC contact with the asymmetry in TSP of tunneling holes. However, the counterpart of n-type SC still needs to be explored.

Here we report the thermal spin injection and accumulation in n-type Ge by employing CoFe/MgO/Ge contacts with the asymmetry in TSP of tunneling electrons. The Joule heating of Ge by electrical current or local heating of CoFe electrode by a laser beam gives rise to a temperature gradient across the tunnel contact and a consequent thermal spin injection into Ge. The thermally-induced spin accumulation was detected by means of the Hanle effect. The sign and magnitude of Hanle signals are analyzed using spin-dependent tunneling theory.

Results

Principle of the approach. Figures 1a and 1b illustrate the thermal spin injection and accumulation process in a FM/oxide/SC tunnel contact for the case that the temperature of SC (TSC) is higher than the temperature of FM
The temperature difference results in the unequal electron distributions in the FM and SC; the hot SC has a relatively larger number of filled (empty) states above (below) the Fermi-level \(E_F\) than those of the cold FM (see Fig. 1b). Consequently, the electrons above \(E_F\) mainly tunnel from the SC into FM (forward tunneling, indicated as (i) in Figs. 1a and 1b), and the electrons below \(E_F\) flow in the opposite direction (reverse tunneling, indicated as (ii) in Figs. 1a and 1b). The important feature of the SST process is that the numbers of electrons tunneling in the opposite direction are the same, and there is no net charge current. Nevertheless, if the energy dependence of TSP is different for the forward and reverse tunneling (in other words, the Seebeck tunnel coefficient for majority and minority spin electrons are different), a spin accumulation (or spin current) can be induced in the SC\(^{20}\). Obviously, the sign of \(\Delta \mu_h\) can be reversed when the temperature gradient is inverted; the cold SC has a relatively smaller number of filled (empty) states above (below) the Fermi-level \(E_F\) than those of the hot FM.

Figure 1c shows the device geometry and measurement scheme used in the present study. We fabricated a symmetric device consisting of three epitaxial CoFe(5 nm)/MgO(2 nm)/n-Ge tunnel contacts \((a\sim c, 100 \times 300 \ \mu m^2)\) where the n-Ge channel is composed of a heavily P-doped surface layer \((n_g \sim 10^{18} \ \text{cm}^{-3} \text{ at } 300 \ \text{K})\) and a moderately Sb-doped substrate \((n_a \sim 10^{18} \ \text{cm}^{-3} \text{ at } 300 \ \text{K})\). These contacts are separated by about 100 nm from each other, which is much longer than the spin diffusion length. The magnetic easy axis of the CoFe contacts are along the [110] direction of Ge in parallel to the long axes of the contacts. Details of the structural and electrical characterizations can be found elsewhere\(^{22,23}\).

To effectively generate the temperature difference \((\Delta T \equiv T_{Ge} - T_{CoFe})\) in the tunnel contact \(a\), we used two different heating methods. For the SC heating (top panel of Fig. 1c), we applied a heating current \(I_{\text{heating}}\) through the SC channel using two contacts \(b\) and \(c\), which causes Joule heating and raises \(T_{Ge}\) with respect to \(T_{CoFe} (\Delta T > 0)\).

For the FM heating (bottom panel of Fig. 1c), the Au bond pad was heated using a laser beam with a wavelength of 532 nm and a maximum power of 200 mW (note that the results obtained with the Joule heating of FM are shown in the Supplementary Information Note I). The laser beam spot (with a diameter of 5–10 µm and a skin depth of ~3 nm) on the 100 nm-thick Au pad is located at around 300 µm from the one edge of the tunnel contact. The size of the Au pad is large enough to prevent the direct illumination of the Ge layer. A part of heat generated from the laser beam passes through the contact, resulting in \(T_{CoFe} > T_{Ge} (\Delta T < 0)\).

In an open-circuit geometry, where the tunneling charge current \(I_{\text{tunnel}}\) is zero, the measured voltage between the contact \(a\) and \(d\) is given by \(V = V_{In} + \Delta V_{TH}^{20}\). The first term \(V_{In}\) is the thermovoltage maintaining zero net charge current \((I_{\text{tunnel}} = 0)\) and the second term \(\Delta V_{TH}\) is the SST voltage due to the induced \(\Delta \mu_h\) in the SC. The \(\Delta V_{TH}\) can be detected by means of the Hanle effect\(^{24,25}\). When we apply magnetic fields \(B_z\) transverse to the spins in the SC, the \(\Delta \mu_h\) is suppressed via spin precession. This results in a voltage change \(\Delta V_{TH}\), directly proportional to \(\Delta \mu_h\), with a Lorentzian line shape as a function of \(B_z\). Two measurement schemes (Fig. 1c) using the Hanle effect\(^{24,25}\) provide a concrete means of demonstrating the SST and resultant \(\Delta \mu_h\) in the SC.

**Energy dependence of tunnel spin polarization in the CoFe/MgO/Ge contact.** Before conducting the thermal spin injection experiments, we have estimated the form of TSP as a function of \(E\), which determine the sign and magnitude of induced \(\Delta \mu_h\) using the conventional three-terminal Hanle (TTH) measurement\(^{20,26}\). Instead of applying \(I_{\text{heating}}\) a non-zero \(I_{\text{tunnel}}\) or \(I_{\text{cool}}\) is applied across the contact \(a\) and \(c\) of the CoFe/MgO/n-Ge contact while the \(V\) is measured using the contact \(a\) and \(d\) in an applied magnetic field (see Fig. 1c). Figure 2a shows the results obtained from the TTH measurements (up to 4 kOe) under perpendicular \((B_z\), closed circles) and in-plane
Figure 2 | Energy dependence of tunnel spin polarization for the CoFe/MgO/n-Ge contact. (a) TTH measurements (up to 4 kOe) for the CoFe/MgO/n-Ge contact under perpendicular ($B_z$, open circles) and in-plane ($B_x$, open circles) magnetic fields at 300 K. (b) Electrical Hanle signals ($\Delta V_{\text{TH, normal}}$ and $\Delta V_{\text{TH, inverted}}$) as a function of an applied current ($I_{\text{ac}}$) at 300 K. (c) Corresponding spin RA products ($\Delta V_{\text{TH, normal}}/I_{\text{ac}}$ and $\Delta V_{\text{TH, inverted}}/I_{\text{ac}}$) and (d) estimated TSP for $\Delta V_{\text{TH, normal}}/I_{\text{ac}}$ with a bias voltage ($V_d = V_{\text{CoFe}} - V_{\text{Ge}}$), defined as $V_{\text{CoFe}} - \Delta V_{\text{TH}}$.

($B_o$, open circles) magnetic fields at RT. Clear electrical Hanle signals ($\Delta V_{\text{TH}}$) with a Lorentzian line shape are detected at RT. It should be noted that the full spin accumulation ($\Delta \mu$) consists of the inverted Hanle signal ($\Delta V_{\text{TH, inverted}}$) in $B_z$ and the normal Hanle signal ($\Delta V_{\text{TH, normal}}$) in $B_x$ [27,28]. As shown in Figs. 2a and 2b, the electrical Hanle signals ($\Delta V_{\text{TH}}$) are significantly asymmetric with respect to the bias polarity, which is consistent with the previous work [29]. Both the $\Delta V_{\text{TH, normal}}$ and $\Delta V_{\text{TH, inverted}}$ increase linearly with increasing the reverse bias current ($I_{\text{ac}} < 0$, electron spin injection), but change slightly with increasing the forward bias current ($I_{\text{ac}} > 0$, electron spin extraction). This asymmetry can also be seen in the middle panel of Fig. 2c, where the spin-RA products ($\Delta V_{\text{RA}}/I_{\text{ac}}$) is plotted as a function of the electrical voltage ($V_d = V_{\text{CoFe}} - V_{\text{Ge}}$). It should be mentioned here that the obtained spin-RA value (2–3 kΩm$^{-1}$) is several orders of magnitude larger than the expected value from the existing spin injection and diffusion theory [3]. This discrepancy between experiment and theory in the TTH measurement has been consistently observed with many types of tunnel barrier and SC, as discussed in the Ref. 3. The origins of this discrepancy, other enhancement factors not yet incorporated in the existing theory, are still under investigation [30].

According to the spin injection and diffusion theory [3], the $\Delta V_{\text{TH, normal}}/I_{\text{ac}}$ is proportional to $\gamma_{d,i}^2/\sqrt{\tau_e}$ at a given temperature ($T$), which depends on $V_d$ (note that, although the existing theory does not provide the quantitative agreement with the experiment, it provides the qualitative description of the TSP variation with $E$). Here, the $\gamma_{d,i}^2$ is the TSP corresponding to the detection of induced spin accumulation at the Ge interface, the $\gamma_{d,i}$ is the TSP of the injected/extracted electrons, and the $\tau_e$ is the spin lifetime. Using the $\Delta V_{\text{TH, normal}}/I_{\text{ac}}$ values (Fig. 2c) and effective ($\tau_{e,i}$) values (not shown) extracted from the Lorentzian fit (black line in Fig. 2a), we plotted the TSP ($\gamma_{d,i}^2/\sqrt{\tau_e}$, normalized) vs. $V_d$ in Fig. 2d. With the assumption of $\gamma_{d,i} = \gamma_{d,i}^0$, the variation of TSP ($\gamma$) with $E$ is then obtained as $\gamma(E) \propto \gamma_0$ for $E < E_F$ (gray line in Fig. 2d) and $\gamma(E) \propto \gamma_0 \exp(-(E - E_F)/0.1)$ for $E > E_F$ (black line in Fig. 2d). The estimated profile of TSP vs. $E$ is indeed similar to the schematically illustrated one on the middle panel of Fig. 1b. This asymmetry in the TSP of CoFe/MgO/n-Ge contacts is essential to induce the large $\Delta \mu_{\text{th}}$ in Ge via the SST [20].

Detection of thermal spin accumulation in Ge. The SST and resultant $\Delta \mu_{\text{th}}$ in Ge were detected in the measurement geometry shown in the top panel of Fig. 1c. While heating the Ge side ($\Delta T > 0$) as described above, the voltage change ($\Delta V_{\text{TH}} \propto \Delta \mu_{\text{th}}$) is measured as a function of the applied magnetic field ($B_z$, $B_x$).

As shown the $\Delta V_{\text{TH}}$–$B_z$ plots in Figs. 3a and 3b, significant normal Hanle signals ($\Delta V_{\text{TH, normal}}$) with the Lorentzian line shape similar to that of $\Delta V_{\text{TH}}$ (see Fig. 2a) were observed at 300 K. The inverted Hanle signals ($\Delta V_{\text{TH, inverted}}$) in $B_z$ (Figs. 3c and 3d), roughly half the magnitude of the $\Delta V_{\text{TH, normal}}$, were also clearly measured. The magnitude of thermal Hanle signals ($\Delta V_{\text{TH}}$) as a function of the $I_{\text{heating}}$ (up to $\pm 10$ mA) is summarized in Figs. 3e–3h. In these figures, we can clearly see that the $\Delta V_{\text{TH, normal}}$ and also $\Delta V_{\text{TH, inverted}}$ scale quadratically with the $I_{\text{heating}}$ and scale linearly with the heating power density ($P_{\text{heating}}$). The $P_{\text{heating}}$ is proportional to $R_{\text{Ge}} I_{\text{heating}}^2 L_z^2 L_y^2$ in Fig. 3e, where the $R_{\text{Ge}}$ is the resistance of the Ge heating layer and the $L_z^2 L_y$ is its volume. These results strongly support that the observed signals mainly come from the thermally driven spin accumulation, which scales linearly with the $\Delta T^{20,30}$, in Ge.

The sign of $\Delta \mu_{\text{th}}$ has been determined by a direct comparison with that of $\Delta V_{\text{TH}}$ obtained from the TTH measurements for the same tunnel contact $a^*$. The sign of $\Delta V_{\text{TH, normal}}$ is negative for...
negative $V_{dd}$ ($V_{CoFe} - V_{Ge} < 0$, electron spin injection) and positive for positive $V_{dd}$ ($V_{CoFe} - V_{Ge} > 0$, electron spin extraction) in Figs. 2(a) and (b). The $\Delta V_{TH, normal}$ in Figs. 3a and 3b has the same sign with the former $\Delta V_{EH, normal}$ ($V_{dd} < 0$), which means that the $\Delta \mu_{th}$ produced by the thermal spin injection has the same sign as the $\Delta \mu_{th}$ induced by the electrical spin injection. Given the positive TSP of epitaxial bcc FM/MgO(001) tunnel interfaces\textsuperscript{31,32}, the $\Delta \mu_{th}$ induced by the SST for $T_{CoFe}$ corresponds to the majority spin accumulation ($\Delta \mu > 0$) in the Ge. This is in agreement with the expected $\Delta \mu_{th}$ from the SST mechanism\textsuperscript{20}; when the TSP of FM/oxide/SC contacts (with positive sign) is constant below $E_F$ but decay above $E_F$ (see Figs. 1b and 2d), majority spins accumulate in the SC ($\Delta \mu > 0$) for $T_{CoFe}$ (see Figs. 1a and 1b). We have calculated that the induced $\Delta \mu_{th}$ is (+)0.26 meV with the maximum $P_{heating}$ (667 nW $\mu$m$^{-2}$) from $\Delta \mu_{th} = (-2e)\Delta V_{TH, normal}^{(+)0.26}$, using the measured $\Delta V_{TH, normal}$ of (-)0.09 mV and the assumed TSP ($\gamma$) of (+)0.7 for the epitaxial CoFe/MgO tunnel interface\textsuperscript{31,32}. This value should be considered as a lower limit for the $\Delta \mu_{th}$, since we used the highest value of TSP. The SST theory\textsuperscript{20} based on the free-electron model predicts the $\Delta \mu_{th}$ value of ~10 μeV for the $\Delta T$ of ~1 K. Considering the possible range of $\Delta T$ across the tunnel contact is from 0.15 mK to 350 mK (see the Supplementary Information Note II), the obtained signal is at least one order of magnitude larger than the predicted value, which was also observed in the Ni$_{80}$Fe$_{20}$/Al$_2$O$_3$/SiO$_2$/p-Si contact\textsuperscript{20}. It is probably due to the limitation of the free-electron model, the lack of detailed information about the energy dependence of TSP near the $E_F$ and the ignorance of inelastic (magnon-assisted) spin tunneling\textsuperscript{20}.

It should be mentioned that our system requires about 100 times larger $P_{heating}$ to obtain a similar magnitude of $\Delta V_{TH}$ compared to the silicon-on-insulator (SOI) wafer based system\textsuperscript{20}. This is mainly attributed to the different device structure. In our device structure,
the $\Delta T$ across the tunnel contact is small because a large part of the Joule heat produced in the heavily-doped Ge layer can flow away to the substrate. The calculated heat flow ratio ($R_{tunnel}$) across the tunnel barrier in our device is more than one order of magnitude smaller than that in the SOI wafer based device\cite{20} (see the Supplementary Information Note I).

**Sign reversal of thermal spin signal by reversing the temperature difference.** Another important feature of SST and $\Delta N_{th}$ is that the sign of the thermal spin signal is reversed when $\Delta T$ is reversed. To demonstrate this, we employed a laser beam for heating the FM instead of the Joule heating method. This approach allows us to heat the FM ($\Delta T<0$) effectively and exclude the contribution of spurious effects such as the current-in-plane (CIP) tunneling and anisotropic magnetoresistance (AMR) on the Hanle signal (see the Supplementary Information Note I).

Figures 4a and 4b show the obtained thermal spin signals as a function of perpendicular ($B_x$, Fig. 4a) and in-plane ($B_y$, Fig. 4b) magnetic fields with varying the laser power density ($P_{laser}$) at RT ($\Delta T<0$). It should be noticed that we used the same contact $a$ (see Fig. 1c) in both cases of the SC and FM heating. Clear normal and inverted Hanle signals are observed and the amplitudes of both Hanle signals are gradually increased with increasing the $P_{laser}$. As shown in the $\Delta V_{TH}\cdot P_{laser}$ plots (Figs. 4c and 4d), the obtained Hanle signals ($\Delta V_{TH,normal}$ and $\Delta V_{TH,inverted}$) scale almost linearly with the $P_{laser}$ indicating that the obtained signal is from the thermal spin injection and accumulation in Ge.

We can see that the sign of $\Delta V_{TH}$ is apparently reversed with respect to the SC heating case: the $\Delta V_{TH,normal}$ ($\Delta V_{TH,inverted}$) is positive (negative) for $T_{CoFe}>T_{Ge}$ (see Figs. 4c and 4d) whereas it is negative (positive) for $T_{Ge}>T_{CoFe}$ (see Figs. 3g and 3h). This result clearly demonstrates another key feature of the SST and $\Delta N_{th}$ that the thermal spin signal reversed when $\Delta T$ is reversed.

In addition, this sign of the Hanle signal allows us to exclude other possible origins for the spin signal, for example, due to the spin-polarized hot-electron injection and conventional Seebeck effect, in the laser-heating experiment. The thermal excitation by the laser heating can result in a current flow in the Au pad and FM layer. Nevertheless, this electrical current cannot be an origin of the observed Hanle signal, since the sign of the observed $\Delta V_{TH,normal}$ (positive sign, see Fig. 4a) for the FM heating ($T_{CoFe}>T_{Ge}$) by the laser beam is opposite to that $\Delta V_{TH,inverted}$ (negative sign) expected by the injection of spin-polarized hot-electron current into the Ge (see the bottom panel of Fig. 2a). This strongly suggests that the observed Hanle signal does not come from the electrical current in the injector.

**Discussion**

For a quantitative analysis, we have calculated the Hanle magnetothermopower (HMTP) (or Hanle magneto-Seebeck ratio ($S_{Hanle}$))\cite{20} defined as the relative change of charge Seebeck coefficient ($S$) due to spin accumulation as follows:

$$ S = \frac{V|_{l_{inverted}} - V|_{l_{normal}}}{\Delta T} = \frac{L}{G} \Delta T + \frac{\gamma \Delta N_{th}}{-2e} \Delta T $$

$$ S_{Hanle} = \frac{\frac{S|_{\Delta T>0} - S|_{\Delta T<0}}{S|_{\Delta T<0}}}{S|_{\Delta T<0}} = \frac{\Delta V_{TH}}{V_{th}} $$

where $G$ is the electrical tunnel conductance, $L$ is the thermoelectric tunnel conductance, $S_0$ is the charge thermopower at zero $\Delta N_{th}$, and $S_{Hanle}$ is the SST coefficient. Figure 5a shows the calculated HMTP (or $S_{Hanle}$) as a function of the $P_{laser}$. The HMTP value of $\Delta V_{TH,normal}/V_{th}$ is $\sim 70$% and remains almost constant with varying the $P_{laser}$. It is important to note that these values are $\sim 70$ times larger than the maximum value ($\sim 0.1$%) of Hanle magnetoresistance (HMR), defined as $\Delta V_{EH}/V_{th}$, obtained by the electrical spin injection using the same contact $a$ (see Fig. 2). This experimental result supports the theoretical proposition\cite{20} that the thermal spin injection is more efficient than the electrical spin.

**Figure 4** Detection of thermal spin accumulation in Ge with heating FM. Obtained thermal spin signals under (a) perpendicular ($B_x$) and (b) in-plane ($B_y$) magnetic fields as a function of the laser power density ($P_{laser}$) at RT in the case of heating the FM ($\Delta T<0$). SCIENTIFIC REPORTS | 2 : 962 | DOI: 10.1038/srep00962
injection for the tunnel contacts with the strong asymmetry in TSP and the moderate thermal interface resistance.

To estimate the value of $S_{\text{STT}}$, defined as $\Delta T_{\text{eff}} / \Delta T^m$, the information of $\Delta T$ across the CoFe/MgO/Ge tunnel contact is required. We carried out the combined analyses using the one-dimensional (1-D) heat flow model and simulation using a commercial finite element software (COVERTOR) to determine $\Delta T$ (see the Supplementary Information Note II). Both the 1-D heat flow model and commercial finite element simulation provide a similar magnitude of $\Delta T$.

Figures 5b and 5c show the representative results of the simulated temperature distribution in a two-dimensional (2-D) cross-section and temperature line-scan across the tunnel contact when heating the Ge with the maximum $P_{\text{heating}}$ of 667 nW $\mu$m$^{-2}$. Here we used a reasonable $\kappa_{\text{eff}}^{\text{MgO}}$ value of 0.04 W m$^{-1}$ K$^{-1}$ (or a $\kappa_{\text{eff}}^{\text{MgO}}$ of $2 \times 10^7$ W m$^{-2}$ K$^{-1}$) for the 2 nm-thick MgO barrier. The possible range of $\Delta T$ across the tunnel contact is from 0.15 mK to 350 mK, and a reasonable $\Delta T$ is an order of 10 mK (see the Supplementary Information Note II for the detailed discussion). Using $\Delta T_{\text{eff}} = 0.26$ meV and $\Delta T = 10$ mK, the $S_{\text{STT}}$ value is estimated to be 26 meV K$^{-1}$ for the CoFe/MgO/n-Ge contact. If we use the largest $\Delta T$ of 350 mK, the $S_{\text{STT}}$ goes down to 0.74 meV K$^{-1}$. These $S_{\text{STT}}$ values are comparable to those of the Ni$_{80}$Fe$_{20}$/Al$_2$O$_3$/SiO$_2$/p-Si contact$^{20}$ but they are at least two orders of magnitude larger than the spin Seebeck coefficient (−3.8 μV K$^{-1}$) of the Co/Cu metallic system$^{13}$, which may be attributed to the different spin injection/detection efficiency and the different measurement scheme.

In conclusion, we have observed the thermal spin injection and accumulation in CoFe/MgO/n-type Ge contacts using local heating of electrodes by laser beam or electrical current. We demonstrate that the magnitude of thermally injected spin signal scales linearly with the power of local heating of electrodes, and its sign is reversed as we invert the temperature gradient. Based on the Seebeck spin tunneling theory, we have obtained a large Hanle magnetothermopower (HMTP) of about 7.0% and the Seebeck spin tunneling coefficient of larger than 0.74 meV K$^{-1}$ in the CoFe/MgO/n-Ge contact at room temperature. This is attributed to the strong asymmetry in the TSP of the contact. Our experimental results demonstrate that the thermal spin injection is an efficient way of spin injection in SC.

**Methods**

**Device fabrication.** The single crystalline CoFe(5 nm)/MgO(2 nm)/n-Ge(001) tunnel structures were prepared by molecular beam epitaxy (MBE) system with a base pressure better than $2 \times 10^{-10}$ torr. Prior to the deposition of CoFe/MgO layers, the composite n-Ge consisting of a heavily p-doped surface layer ($n_d \sim 10^{19}$ cm$^{-3}$ at 300 K) and a moderately Sb-doped substrate ($n_d \sim 10^{15}$ cm$^{-3}$ at 300 K) was formed by ion implantation technique. All layers were deposited by e-beam evaporation with a working pressure better than $2 \times 10^{-4}$ torr. The MgO and CoFe layers were grown at 125°C and RT, respectively, and the samples were subsequently annealed in-situ for 30 min at 300°C below $2 \times 10^7$ torr to improve the surface morphology and crystallinity. Finally, the samples were capped by a 2 nm thick Cr layer at RT to prevent oxidation of the sample. The symmetric device (Fig. 1c) consisting of three tunnel contacts with lateral sizes of 100 nm/300/100 nm was prepared by using micro-fabrication techniques (e.g., photo-lithography and Ar-ion beam etching) for the thermal spin accumulation experiments. For the electrical isolation at the sides of the tunnel contacts, about 120 nm-thick Ta$_2$O$_5$(115 nm)/Al$_2$O$_3$(2 nm) layers were grown by sputtering technique. For the contact pads, 110 nm-thick Au(100 nm)/Ti(10 nm) layers were deposited.

Acknowledgements
This work was supported by the DGIST R&D Program of the Ministry of Education, Science and Technology of Korea (11-IT-01); by the KIST institutional program (2E22732 and 2Y0272O) and by the Pioneer Research Center Program (2011-0027903); and by the KBSI grant no.T32517 for S-YP.

Author contributions
S.-C.S. supervised the project; K.-R.J. designed and conducted the experiments with the help of B.-C.M.; K.-R.J. prepared the samples; K.-R.J. and Y.-H.P. carried out the patterning process; K.-R.J. carried out the measurements; S.-Y.P., K.-D.L., H.-S.S. and Y.-H.J. contributed to the measurement setups; K.-R.J., B.-C.M. and S.-C.S. conducted theoretical analysis and wrote the manuscript.
