Placental Adiponectin Gene DNA Methylation Levels Are Associated With Mothers’ Blood Glucose Concentration

Luigi Bouchard,1,2 Marie-France Hivert,3 Simon-Pierre Guay,1,2 Julie St-Pierre,4 Patrice Perron,2,3 and Diane Brisson2,5

Growing evidence suggests that epigenetic profile changes occurring during fetal development in response to in utero environment variations could be one of the mechanisms involved in the early determinants of adult chronic diseases. In this study, we tested whether maternal glycemic status is associated with the adiponectin gene (ADIPOQ) DNA methylation profile in placenta tissue, in maternal circulating blood cells, and in cord blood cells. We found that lower DNA methylation levels in the promoter of ADIPOQ on the fetal side of the placenta were correlated with higher maternal glucose levels during the second trimester of pregnancy (2-h glucose after the oral glucose tolerance test; \( r_s = -0.21, P < 0.05 \)). Lower DNA methylation levels on the maternal side of the placenta were associated with higher insulin resistance index (homeostasis model assessment of insulin resistance) during the second and third trimesters of pregnancy (\( r_s = -0.27, P < 0.05 \)). Finally, lower DNA methylation levels were associated with higher maternal circulating adiponectin levels throughout pregnancy (\( r_s = -0.26, P < 0.05 \)). In conclusion, the ADIPOQ DNA methylation profile was associated with maternal glucose status and with maternal circulating adiponectin concentration. Because adiponectin is suspected to have insulin-sensitizing proprieties, these epigenetic adaptations have the potential to induce sustained glucose metabolism changes in the mother and offspring later in life.

With a prevalence ranging from 6.5 to 18%, gestational diabetes mellitus (GDM) is responsible for most cases of hyperglycemia during pregnancy, and its occurrence is set to grow rapidly in response to the worldwide epidemic of obesity (1). In accordance with the fetal programming (Barker) hypothesis, maternal hyperglycemia has been associated with an increased long-term risk of overweight and type 2 diabetes in offspring in many studies (2). Maternal hyperglycemia during pregnancy is consequently a major public health concern. The development of obesity-related metabolic perturbations may start very early in life, as indicated by recent studies where glucose metabolism impairment was observed in the offspring of mothers with GDM as young as 3 years of age (3–5). Of interest, exposure to an adverse fetal environment will potentially have transgenerational effects, suggesting that an initial exposure to an adverse fetal environment may have health consequences on multiple generations (6–9). Accordingly, it is expected that the increasing prevalence of GDM will result in a worsening of the prevalence of obesity and its related disorders, feeding a vicious circle.

Exact mechanisms involved in fetal programming remain to be discovered, including the possible transgenerational effect. Epigenetic phenomena have been repeatedly proposed as molecular mechanisms that could explain how a detrimental fetal environment can be associated with obesity and type 2 diabetes years after exposure, but only a few studies have addressed this hypothesis directly. Epigenetics refers to the heritable, but also reversible, regulation of DNA transcription (10), a mechanism independent of the DNA sequence. Epigenetic marks are subject to reprogramming in response to both stochastic and environmental stimuli, such as the in utero environment (11–13). The DNA methylation occurring at position 5’ of the cytosine pyrimidine ring is the more stable and best-understood epigenetic system (14). Cytosine methylation is frequently observed at CpG dinucleotide loci. A high level of methylation is associated with a lower transcription of the target genes (15,16).

The placenta plays a critical role in embryo and fetus growth and is responsive to environmental changes. It is metabolically very active and is central in the nutrient and waste exchange between the fetus and the mother. Therefore, the placenta is a unique tissue with which to study the molecular impacts of GDM (17). A few studies suggest that epigenetic gene transcription regulation contributes to explain the long-term influence of GDM on childhood health (18,19). Very recently, the level of DNA methylation of a number of epivariants has been shown to be altered in the placenta of newborns of low birth weight (20,21). These results suggest that the DNA methylation profile of human term placenta reflects the fetal growth and development with a potential impact on the newborn’s health (20,21). Accordingly, DNA methylation changes in the placenta also will likely influence the chromatin structure and thus the transcription of key energy metabolism and type 2 diabetes expression genes such as adiponectin.

Adiponectin is the most abundant circulating hormone secreted by the adipocytes, with putative insulin-sensitizing, anti-inflammatory, and antiatherosclerotic properties (22). In a normal pregnancy, the maternal adiponectin circulating concentration increases in the first half of the pregnancy and then decreases proportionally to weight gain and physiological insulin resistance worsening (22). Newborn adiponectin concentrations are higher than maternal circulating levels during pregnancy (22). Overall, it suggests that adiponectin, in addition to potentially linking excess adiposity to the risk of insulin resistance and type 2 diabetes, has a potential role in pregnancy and fetal growth (22).

In the current study, we tested whether cytokines located at ADIPOQ gene proximal promoter CpG islands...
ADIPONECTIN GENE EPIGENETIC CHANGES IN GDM

habor DNA methylation changes in placental tissues, maternal circulating blood cells, and cord blood cells are associated with maternal glucose levels during pregnancy.

RESEARCH DESIGN AND METHODS

Ninety-eight women with a singleton pregnancy were recruited during their first trimester of pregnancy in the Saguenay area from a founder population of French-Canadian origin (self-reported and confirmed by last name and first language). They were all followed until delivery with three visits (at the end of the first trimester of pregnancy) at the research center, and samples were collected at each visit and at delivery. Women aged ≥40 years, with pre-GDM or other disorders (polycystic ovarian syndrome, uncontrolled thyroid disorders, and renal insufficiency) known to affect glucose metabolism, as well as those with a positive history of alcohol and/or drug abuse during the current pregnancy, were excluded. The Chicoutimi Hospital Ethics Committee approved the project. All women provided written informed consent before their inclusion in the study, in accordance with the Declaration of Helsinki.

BMI was measured according to the standardized procedures of the Airfile conference (23). Blood samples were collected after a 12-h fast. Blood glucose and insulin measurements were performed on fresh serum samples at the Chicoutimi Hospital Clinical Laboratory. Glucose was evaluated using a Beckman analyzer (model CXT; Beckman, Fullerton, CA), and insulin measurements were performed using an enzyme-linked immunosorbent assay, as recommended by the manufacturer (B-Bridge International). Homeostasis model assessment of insulin resistance (HOMA-IR) was calculated using the following equation (24): HOMA-IR = fasting insulin (mU/L)/22.5. Serum adiponectin levels were measured using an enzyme-linked immunosorbent assay, as recommended by the manufacturer (PyroMark Q24; Qiagen-Biotage). In brief, methylated cytosines are protected against a C→T transition following sodium bisulfite treatment (EpiTect Bisulfite Kit; Qiagen). Pyrosequencing is a quantitative sequencing method allowing the quantification (%) of cytosine methylation levels at each CpG site of a given genomic region. PCR primers were selected using the PyroMark Assay Design (version 2.0.1.15; Qiagen). The PCR and pyrosequencing primers for all three CpG islands tested within the ADIPQ gene locus were AdipQ-F: 5’-GGATTTTATTTAGGAGGTGATAGTTTAA-3’; AdipQ-R: 5’-ACCTAAACCTCCCCTTTCACC-3’ (161 bp), and AdipQ-Seq: 5’-TTTTTATTTAGGAGGTGATAGTTTTT-3’ (9 CpGs); AdipQ1F: 5’-GTTGTTGAGGAGGTGATAGTTTTAATTTAAA-3’; AdipQ1R: 5’-ACCTCCACCTCCAAATATCCAG-3’ (190 bp), and AdipQ1Seq: 5’-ACCCTAAACCTCCCCTTTCACC-3’ (161 bp); AdipQ2F: 5’-TTTGGTGTGAGGAGGTGATAGTTTTTTTTT-3’; AdipQ2R: 5’-ACACACACCTCCACCTCTAGTAT-3’ (180 bp), and AdipQ2Seq: 5’-CAACACACCTCCACCTCTAGTAT-3’ (161 bp). One of 98 DNA samples (from the mother’s side) did not amplify and therefore was not analyzed.

cDNA was generated from total RNA using a random primer hexamer provided with the High Capacity cDNA Archive Kit (Applied Biosystems, Foster City, CA). Equal amounts of cDNA were run in duplicate and amplified in a 20-μL reaction containing 10 μL of 2× Universal PCR Master Mix (Applied Biosystems). Primers and Taqman probes were obtained from Applied Biosystems (ADIPQ: Hs00605917_m1; Applied Biosystems). The YWHAZ housekeeping gene (endogenous control; YWHAZ: Hs00227047_m1) was amplified in parallel. ADIPQ and YWHAZ amplifications were performed using an Applied

Placenta tissue sampling. Placenta tissue was sampled in the minutes following delivery (on average <15 min) by well-trained clinicians (MD) and kept in RNA-Later (Qiagen, Valencia, CA) at ~80°C until nucleic acid extraction. Tissue biopsies were collected from both fetal and maternal sides. The former consisted of the intervillous tissues and chorionic villi, and the latter consisted mainly of fetal villous tissue but also contained tissue of maternal origin in the decidua basalis (basal plate). Analyses were performed on both sides independently.

ADIPQ DNA methylation and mRNA level measurements. DNA and RNA were purified from placenta biopsies using the All Prep DNA/RNA/Protein Mini Kit (Qiagen). DNA was purified from whole-blood and cord-blood samples with the Gentra Puregene Cell Kit (Qiagen). RNA quality was assessed with Agilent 2100 Bioanalyzer RNA Nano Chips (Agilent Technology). On average, the RNA showed good integrity (mean RNA integrity 7.99 ± 0.77).

DNA methylation levels at CpG sites were assessed using pyrosequencing (Pyromark Q24; Qiagen-Biotage). In brief, methylated cytosines are protected against a C→T transition following sodium bisulfite treatment (EpiTect Bisulfite Kit; Qiagen). Pyrosequencing is a quantitative sequencing method allowing the quantification (%) of cytosine methylation levels at each CpG site of a given genomic region. PCR primers were selected using the PyroMark Assay Design (version 2.0.1.15; Qiagen). The PCR and pyrosequencing primers for all three CpG islands tested within the ADIPQ gene locus were AdipQ-F: 5’-GGATTTTATTTAGGAGGTGATAGTTTAA-3’; AdipQ-R: 5’-ACCTAAACCTCCCCTTTCACC-3’ (161 bp), and AdipQ-Seq: 5’-TTTTTATTTAGGAGGTGATAGTTTTT-3’ (9 CpGs); AdipQ1F: 5’-GTTGTTGAGGAGGTGATAGTTTTAATTTAAA-3’; AdipQ1R: 5’-ACCTCCACCTCCAAATATCCAG-3’ (190 bp), and AdipQ1Seq: 5’-ACCCTAAACCTCCCCTTTCACC-3’ (161 bp); AdipQ2F: 5’-TTTGGTGTGAGGAGGTGATAGTTTTTTTTT-3’; AdipQ2R: 5’-ACACACACCTCCACCTCTAGTAT-3’ (180 bp), and AdipQ2Seq: 5’-CAACACACCTCCACCTCTAGTAT-3’ (161 bp). One of 98 DNA samples (from the mother’s side) did not amplify and therefore was not analyzed.

cDNA was generated from total RNA using a random primer hexamer provided with the High Capacity cDNA Archive Kit (Applied Biosystems, Foster City, CA). average, women were slightly overweight at the first trimester of pregnancy and were generally metabolically healthy, all having a normal fasting glucose concentrations. Thirty-one women were classified as having IGT, and 67 were normoglycemic according to the World Health Organization guidelines (28). Only two women fulfilled the American Diabetes Association criteria for GDM diagnosis (29). As expected, higher adiponectinemia in cord blood was associated with a higher birth weight ($r_s = 0.26$, $P = 0.02$) (30).

**DNA methylation analyses and genomic context.** A total of 17 CpGs located within three ADIPOQ locus CpG islands were epigenotyped. CpG islands and the results are illustrated in Fig. 1. The most upstream CpG island (A3) investigated is located roughly 20 kb from the first exon. The nine CpGs tested at this locus demonstrated very low levels of methylation (mean DNA methylation = 2.7%), and thus the results were not analyzed. The second CpG island (C1) is located within the proximal promoter region (4 kb upstream the first exon). The four CpGs investigated within the C1 locus showed average methylation levels $\sim$30% (C1_mean). Finally, the third CpG island (E2) is located between the first and second exons. Mean DNA methylation levels were, on average, between 85% (CpGs 1 and 2; E2_mean1) and 63% (CpGs 3 and 4; E2_mean2), depending on their location within the island. Although mean DNA methylation levels between both placenta sides were similar, the cytosine methylation level correlations between both placenta sides were found to be generally weak and not significant for most of the 17 CpGs tested (C1_mean: $r_s < 0.19$, $P = 0.07$; E2_mean1: $r_s < 0.09$, $P = 0.37$; and E2_mean2: $r_s < 0.10$, $P = 0.32$).

Nevertheless, DNA methylation levels generally were found to be well correlated between CpG sites within the C1 and E2 CpG islands. They were analyzed together when the correlation coefficient was $\geq 0.60$, resulting in three separate means (C1_mean, E2_mean1, and E2_mean2; as illustrated in Fig. 1).

DNA methylation levels at these 17 loci also were measured in DNA extracted from circulating blood cells (maternal and cord blood). Again, cytosines within the A3 island were found to be unmethylated, whereas cytosines in both C1 and E2 loci were fully methylated (tested in 10 samples each; data not shown).

**Correlations between maternal glucose levels and DNA methylation levels in placental tissues.** A higher level of maternal glucose at 2 h post-OGTT was associated with lower mean DNA methylation levels at the C1 (CpG 1–4) and E2 (CpGs 3 and 4) CpG islands on the fetal side of the placenta (Table 2 and Fig. 2). Adjusting the statistical models for weight gain over pregnancy as a potential confounder did not affect the relationship significantly (Table 2). Results remained unchanged after further adjustment for HOMA-IR (results not shown). Mean DNA methylation differences in the fetal side of the placenta between women who were normoglycemic (normal glucose tolerance [NGT]) and those who had IGT also were analyzed. We found that E2_mean2 DNA methylation levels were slightly lower in the group with IGT compared with women with NGT (67.03 ± 0.65% vs. 64.92 ± 0.96%), but the comparison did not reach statistical significance ($P = 0.07$). A higher maternal insulin resistance at the second and third trimesters reflected by an increased HOMA-IR value was associated with lower DNA methylation levels (mainly at the E2 CpG island) on the maternal side of the placental tissue (Table 2). Adjustment for the corresponding trimester circulating adiponectin concentration substantially improved the relationship (Table 2). Correlations remained significant after excluding the women taking insulin as a treatment for their GDM.

**FIG. 2.** Spearman correlation between placental ADIPOQ gene promoter DNA methylation and 2-h post-OGTT glucose levels. Adjusted for weight gain between the first and third trimester ($n = 98$).
DNA methylation analyses were conducted on DNA extracted from placenta biopsies. *Adjusted for the mother’s BMI at the first trimester of pregnancy and HOMA-IR at the second trimester of pregnancy. Trends (P ≤ 0.1) and significant correlations (P ≤ 0.05) are shown in boldface type.

**DISCUSSION**

The intrauterine life is a critical period suspected to impact the long-term programming of the energy homoeostasis regulation and consequently plays an important role in developing obesity and type 2 diabetes. This observation is biologically plausible knowing that glucose, per se, could inﬂuence by glucose levels throughout the full gestational period, arguing for the importance of glycemic levels in response to glucose intake for determining children’s susceptibility to obesity and type 2 diabetes (31,32). However, the molecular mechanisms determining children’s susceptibility to obesity and type 2 diabetes are poorly understood.

DNA methylation analyses were conducted on DNA extracted from placenta biopsies. *Adjusted for the mother’s BMI at the first trimester of pregnancy and HOMA-IR at the second trimester of pregnancy. Trends (P ≤ 0.1) and significant correlations (P ≤ 0.05) are shown in boldface type.
that high maternal glucose concentrations lying below the American Diabetes Association cutoff for GDM is associated with excess adiposity in childhood (35), suggesting that a slight increase of glycemia could be associated with detrimental long-term health effects for the offspring and should be prevented when possible. In the current study, we have shown that even intermediate glucose intolerance is correlated with the \textit{ADIPOQ} DNA methylation profile. This evidence supports the use of more inclusive GDM cutoff values, such as the ones suggested by the International Association of Diabetes and Pregnancy Study Groups to reduce as much as possible hyperglycemia deleterious effects on newborns' health (34).

It also has been suggested that adiponectin down-regulates its own production via a regulatory feedback loop (36). However, adiponectin does not pass through the placental barrier (22) (similarly to insulin), so it is unlikely that maternal adiponectin levels influence DNA methylation on the fetal side. However, it is likely that the association between fetal-side DNA methylation levels and maternal adiponectin levels reflect some common factors associated with both. Many factors influencing the \textit{ADIPOQ} gene DNA methylation profile remain to be identified because our model only partially explains ($r_s = -0.28$) its interindividual variability. Research to identify those factors should be undertaken.

With regards to the maternal side of the placenta, a higher maternal insulin resistance was associated with lower DNA methylation levels at the \textit{ADIPOQ} locus, and this association was strengthened after adjusting for circulating adiponectin concentrations. Our results suggest that insulin resistance is correlated with \textit{ADIPOQ} DNA methylation levels in maternal tissues. Moreover, we showed that DNA methylation at the \textit{ADIPOQ} gene locus was correlated with circulating adiponectin concentrations at each trimester of pregnancy and postdelivery, which strongly suggests that these epigenetic marks are biologically functional. The correlation between DNA methylation and maternal circulating adiponectin levels also is strengthened by adjustment for HOMA-IR, suggesting that the regulation of the adiponectin expression is influenced by the level of insulin resistance. Because we and others (37,38) showed that the placenta itself does not express adiponectin, our results suggest that placental DNA methylation changes on the maternal side are surrogate measures of the changes taking place in the maternal adipose tissue. However, we cannot exclude that the \textit{ADIPOQ} gene may have been expressed at some point in the placenta during the pregnancy, because the C1 and E2 CpGs islands were not fully methylated, contrary to what was observed in cord and mother circulating blood cells (known not to express \textit{ADIPOQ}). This could explain the controversial results.
published to date about the potential adiponectin production by the placenta (37–39). Nevertheless, our results suggest that the placenta is useful for the study of epigenetic adaptations to the fetal milieu as already suggested (17), even for genes with very low (or absent) expression such as adiponectin.

We confirmed that a higher adiponectinemia in cord blood is associated with a higher birth weight, in line with previous observations (30); this is in contrast to the inverse association between the adiposity status and adiponectin levels in adults. It has been suggested that the number of small healthy adipocytes and a favorable ratio of subcutaneous to visceral fat at birth could explain the positive relationship (30). This is consistent with the Perdersen hypothesis (40,41): maternal glucose crossing the placental barrier stimulates fetal insulin production, leading to growth of the baby, including adipose tissue differentiation and expansion and, by consequence, higher adiponectin levels in cord blood at birth. Nevertheless, there also is data showing that newborns from mothers with GDM have lower adiponectin levels (42), suggesting that the adipose tissue already could be affected by adverse events occurring in utero. In our sample, only two women were classified as having GDM; therefore, we could not confirm this observation and test whether GDM was associated with a different DNA methylation pattern.

Although it has been suggested that epigenetic marks can be short-lived and rapidly reversed, it is well accepted that they are mitotically stable and relatively enduring, with only marginal changes over time, producing long-term changes to gene expression (11,13,43–45). Therefore, we propose that the initial ADIPOQ gene DNA methylation profile of an individual, partially determined by the fetal milieu, will contribute to limiting or worsening the switch from a positive correlation with weight at birth to a negative one later in life in response to aging and environmental and metabolic factors. This could be associated with an increased risk or not of developing obesity and type 2 diabetes.

**Strengths and limitations.** Among the strengths of our study, the longitudinal follow-up starting at the first trimester with standardized testing for glucose regulation allowed us to correctly identify women with de novo IGT during pregnancy and avoided misclassifications (46). The technologies used for genotyping and measures of DNA methylation levels are well validated and reliable. Our sample size was fairly large compared with other studies looking at epigenetic mechanisms and allowed us to take into account possible confounding factors. Nevertheless, our study also has limitations. We interpreted the association between maternal adiponectin levels and placental DNA methylation at the ADIPOQ locus as being a reflection of maternal adipose tissue (as the only human tissue known to produce and secrete adiponectin). Unfortunately, adipose tissue was not available to confirm these associations. This study was conducted in a homogeneous population from European descent, which is a strength in genetics and epigenetics studies, but our findings might not be applicable to other populations.

**Conclusions.** It is expected that the number of women affected by hyperglycemic disorders in pregnancy will increase in association with the growing prevalence of obesity. We also know that in utero exposure to hyperglycemia increases the risk of obesity and insulin resistance in offspring, feeding forward the vicious circle. Our results suggest that epigenetic changes around ADIPOQ could be one of the mechanisms involved in fetal programming of metabolic
disorders of adult life. Investigations concerning other genes in energy balance, glycemic regulation, and insulin resistance pathways, including functional studies, will be essential to confirm our findings. Identification of molecular mechanisms and genes involved in the fetal programming of energy metabolism will improve our understanding of the pathophysiological processes involved in metabolic disorders and, hopefully, help to limit the vicious cycle contributing to the actual obesity/diabetes epidemic.
