Abstract

This paper concerns development of a high-performance implementation of the Particle-in-Cell method for plasma simulation on Intel Xeon Phi coprocessors. We discuss suitability of the method for Xeon Phi architecture and present our experience of porting and optimization of the existing parallel Particle-in-Cell code PICADOR. Direct porting with no code modification gives performance on Xeon Phi close to 8-core CPU on a benchmark problem with 50 particles per cell. We demonstrate step-by-step application of optimization techniques such as improving data locality, enhancing parallelization efficiency and vectorization that leads to 3.75\texttimes speedup on CPU and 7.5\texttimes on Xeon Phi. The optimized version achieves 18.8 ns per particle update on Intel Xeon E5-2660 CPU and 9.3 ns per particle update on Intel Xeon Phi 5110P. On a real problem of laser ion acceleration in targets with surface grating that requires a large number of macroparticles per cell the speedup of Xeon Phi compared to CPU is 1.6\texttimes.

1. Introduction

The progress in high intensity laser pulse generation throughout the last 20 years has stimulated theoretical and experimental research on ultra-intense laser-matter interaction in extremely relativistic regimes \cite{1, 2}. This is valuable
for both fundamental research on physics of matter in extreme conditions and various applications. The notable directions are: laser-driven electron acceleration to the ultrarelativistic energies \cite{3}, acceleration of ion beams to tens and hundreds MeV / nucleon \cite{4, 5}, generation of X-ray and gamma ray radiation including pulses of atto- and zeptosecond duration \cite{6}, and QED effects in ultrahigh intensity field, namely electron-positron pair production and nonlinear optics of vacuum \cite{6, 8}. The applications are fast ignition of inertial confinement fusion targets \cite{9}, hadron therapy for cancer treatment \cite{10}, protonography, x-ray imaging \cite{11}, etc.

High intensity laser-matter interaction involves several nonlinear physical phenomena: relativistic and ponderomotive self-focusing, collisionless heating, various plasma instabilities, high harmonics generation, and others. The proper analytical examination is only possible in several simple cases. Thus, one of the main tools for theoretical research is numerical simulation. Along with investigation of the underlying physics, computer simulation helps to set experiments by allowing faster and more efficient adjustment of parameters for laser and target, designing experimental schemes, and interpretation of the results.

The most widely used method for simulation of plasma in ultrahigh field is the Particle-in-Cell (PIC) method \cite{12}, which allows to perform full 3D simulations that capture the main processes governing laser-plasma interaction. The computational complexity of the Particle-in-Cell method is relatively low compared to other kinetic methods (e.g. Euler \cite{13}), yet large-scale 3D simulation requires high-performance implementation aimed at supercomputers. Currently, several widely known implementations of the fully relativistic Particle-in-Cell method are capable of 3D large-scale plasma simulation on supercomputers, most notably, OSIRIS \cite{14}, VPIC \cite{15}, VLPL \cite{16}, WARP \cite{17}, PIConGPU \cite{18}. The striking example of continuous progress in accelerating the simulation in terms of both algorithms and implementation efficiency is a relativistic boosted frame that allows to speed up simulations of laser propagation in low density plasma by a factor of tens \cite{17}.

Heterogeneous cluster systems are based not only on convenient CPUs, but also on different types of accelerators, including GPUs and the recently introduced Intel Xeon Phi coprocessors. This results in a growing interest in Particle-in-Cell adaptations for such systems. While the Particle-in-Cell method is generally suitable for modern GPUs, its efficient implementation requires a meticulous approach to data structures and parallel processing schemes as well as conscious usage of different layers of GPU memory and is by no means a simple port of an efficient implementation for CPUs.

Although several successful porting of applications to Xeon Phi coprocessors have been reported recently \cite{19, 21}, it is not certain if a significant portion of peak performance is achievable for a wide class of applications, and does efficient porting of an existing application require code tuning in scope of OpenMP or rather massive rewriting similar to porting to GPUs. A brief analysis shows that although a straightforward porting can be done very quickly even for a large application, it will be efficient only if the application was properly optimized for CPUs and has a large degree of parallelism on thread-level and SIMD-level.
This might be a limiting factor, as many implementations scale well up to 8–16 threads, but not up to 120–240 threads or are only capable of using low width SIMD. Another obstacle similar to GPUs might be a small amount of memory, which on Xeon Phi is only 6–16 GB. Thus, a no-effort "just rebuild" porting does not seem to be efficient except some very special cases, at the same time a porting with reasonable additional tuning seems promising.

This paper presents our experience with porting the existing parallel Particle-in-Cell plasma simulation code PICADOR \cite{22, 23} to Xeon Phi coprocessors. We demonstrate a step-by-step optimization process with iterative bottleneck analysis and application of optimization techniques. We believe that the encountered problems and applied optimizations are not specific to the Particle-in-Cell implementation and similar ideas are useful for a wide class of applications. We illustrate porting and optimization of the code on CPUs and Xeon Phi coprocessors. We use a benchmark frozen plasma simulation problem with ideal balance and no MPI exchanges. The performance of the final version is then evaluated on a real problem of laser ion acceleration in targets with surface grating. This problem is shown to be demanding a high number of macroparticles which makes it highly suitable for acceleration by means of Xeon Phi coprocessors.

The paper is organized as follows. The Particle-in-Cell method is briefly described in section 2. In section 3 we discuss suitability of the method for Xeon Phi coprocessors and optimization methodology. We present experience of porting and optimization of the Particle-in-Cell plasma simulation code PICADOR to Xeon Phi in section 4. Section 5 contains performance evaluation of a real simulation.

2. Particle-in-Cell Method

This section briefly describes the Particle-in-Cell method in the form used in our implementation, a detailed description is given in \cite{12}.

The simulation area is a 3D axis-aligned parallelepiped covered by uniform spacial grid. Dynamics of the electric field $E$ and magnetic field $B$ is defined by the Maxwell’s equations solved on the grid using the FDTD method \cite{24}. Plasma is represented as an ensemble of $N$ charged quasi-particles, each with a variable momentum $p$ and position $r$, and constant mass $m$ and charge $q$. The position and velocity $v$ evolve according to Newton’s law in relativistic form that is numerically integrated using Boris method. Particles motion creates electric current $j$ that is a part of Maxwell’s equations, enclosing the self-consistent system of equations.

A basic computational scheme of the Particle-in-Cell method with the main equations and data dependencies is given in Fig. 1. An iteration of the computational loop corresponds to a time step. Each time step consists of 4 main stages. Field solver updates grid values of the electromagnetic field. Field interpolation from the grid to particle position is performed to compute the Lorenz force affecting particles. Solving equations of particle motion is used to push particles one step further. The computational loop closes with computation of current created by particle motion. In terms of software implementation
it is convenient to merge the field interpolation, force computation and solving equations of particle motion into one stage, referred as particle push. The Particle-in-Cell method can be extended in many ways [25], in this paper we consider only the basic version of the method as these stages take significant share of computational time even in more complicated simulations.

The Particle-in-Cell method operates on two principally different data sets: an ensemble of charged particles with continuous coordinates and values of the field and current density set on a discrete grid. The most time consuming stages of particle push and current deposition operate on both data sets, thus implementation of these stages plays a major role in both accuracy and computational efficiency.

3. Implementation of the Particle-in-Cell Method for Xeon Phi Co-processors

In this section we analyze suitability of the Particle-in-Cell method for Xeon Phi coprocessors and discuss optimization techniques required to achieve good performance. There are several highly efficient implementations of the method for GPUs [18] which implies good suitability for Xeon Phi as well. However, there are several Xeon Phi-specific features and considerations.

3.1. Overview of Xeon Phi Coprocessors

A Xeon Phi coprocessor has 60 cores (61 on some modifications) on shared memory with Linux on board. The cores are x86-compatible, but have simplified architecture compared to CPU cores with no support to out-of-order
execution and branch prediction, combined with wider 512-bit vector registers (256-bit on modern CPUs). Each core supports up to 4 hardware threads, it is recommended to run at least 2 threads per core. The peak performance of a Xeon Phi core is lower than of a modern CPU core, but larger number of cores provides overall nearly 1 TFLOPS peak performance in double precision. Another notable advantage over CPUs is GDDR5 memory with about 350 GB/s peak throughput, 5 to 10 times larger compared to CPUs.

Programming for Xeon Phi can be done using traditional programming languages and parallel programming libraries: C, C++, Fortran languages, MPI, OpenMP, Cilk Plus, OpenCL, TBB and MKL libraries. This significantly simplifies porting of existing applications as the vast majority of code (or even full code) does not need to be modified for Xeon Phi. There are three execution modes: running only on Xeon Phi as a multicore processor (native mode), running the main program on a CPU and calling computational cores on a coprocessor similar to GPU usage (offload), running some MPI processes on CPUs and some on Xeon Phi coprocessors (symmetric).

Overall, Xeon Phi has manycore architecture with wide vector registers and high throughput memory. Parallelism on both thread level (120–240 threads) and 512-bit SIMD level is crucial for good performance. Although existing applications can generally be ported without any significant effort, performance of such ports is not guaranteed even for implementations that are efficient on CPU. Some additional optimization and tuning is most likely required. However, the main optimization principles for CPU and Xeon Phi coprocessors are similar, so optimization for one of the platforms is likely to yield benefit for the other.

3.2. Analysis of Suitability of the Particle-in-Cell Method for Xeon Phi Coprocessors

Generally there are several fundamental factors that determine applicability of accelerators such as GPUs and Xeon Phi coprocessors. First, there is a memory limitation of 6 to 16 GB RAM per accelerator which is coupled with a PCI Express bus to the host. While this could be very restrictive for applications working with large sets of data, Particle-in-Cell simulations are spatially local, thus allowing to efficiently decompose a problem between many computational nodes and fit memory limitations of a node.

Performance-wise Xeon Phi coprocessors offer about 5x peak performance advantage over top server CPUs. Achieving a significant share of peak performance is challenging on CPUs and even more so on Xeon Phi coprocessors. However, a half of peak performance of Xeon Phi is attributed to vector fused multiply-add (FMA) instruction that performs two floating-point operations at once. Obviously, real applications do not consist of sequences of pure FMA calls and not utilizing FMA effectively reduces performance by half.

Efficient utilization of Xeon Phi requires excellent scaling on shared memory. Coprocessors offer 60 cores with up to 4 hardware threads. Well-suited applications usually either scale well up to 120–240 threads or use efficient hybrid MPI + OpenMP parallel scheme. One way or another, the method must have a significant parallelization potential. An ideal application in this regard
(for pretty much all parallel hardware) is a Monte-Carlo method, which allows ideal scaling. The Particle-in-Cell method also allows ideal scaling on shared memory CPU cores and, in our experience, 75% scaling efficiency on Xeon Phi cores (for large number of particles per cell). It is important to note that good scalability is only the necessary condition for efficient utilization of Xeon Phi, but not sufficient.

Another important — and often the most challenging — factor is utilization of vector units for performing floating-point operations, so-called vectorization. Vectorization is important for CPUs, and even more so on Xeon Phi due to 512-bit vector registers compared to 256-bit on modern CPUs. As consequently, vectorization theoretically offers double dividend on Xeon Phi compared to CPUs and lack of vectorization puts double penalty on Xeon Phi performance. The Particle-in-Cell method is not an easy candidate for vectorization. A straightforward implementation of field interpolation and current deposition in 3D results in non-unit stride (not local) memory access pattern that is detrimental to vectorization. A special organization of those operations is required to allow proper vectorization.

Our analysis shows that the Particle-in-Cell method, although not ideally suited for Xeon Phi coprocessors due to vectorization issues, is a promising candidate. We will show that with proper programming a Xeon Phi coprocessor can achieve about 2x speedup over a tuned implementation on a modern 8-core CPU on both benchmark and simulation of the real problem.

3.3. Optimization Methodology

Although some computational applications are developed for specific class of hardware and thus could largely benefit from hardware-specific features, the vast majority of applications are initially developed for CPUs and then ported to accelerators. This subsection is devoted to general discussion of porting and optimization of an existing computational application from CPUs to accelerators. We suppose the numerical schemes being used are suited for parallel processing and the code is developed using standard for HPC programming languages C, C++ or Fortran and parallel programming technologies MPI and OpenMP.

By all means, one should start with optimization for modern CPUs mainly focusing on scaling efficiency and vectorization. In most cases this optimization is beneficial for Xeon Phi as well. An existing code can be ported to Xeon Phi by just recompiling it with Intel Compiler; this is a substantial advantage of Xeon Phi over GPUs that generally require significant modification of the code. In our experience this "no-effort" port usually requires several minutes in an ideal case to several hours, mostly spent on rebuilding third-party libraries. Performance of such port can be discouraging even for codes that are fairly efficient on CPUs. It is essential to use profiling tools to discover the most time-consuming routines and performance-limiting factors. Pieces of code that were fast enough to not optimize and parallelize on CPU often become a bottleneck on Xeon Phi due to larger amount of cores and poor single-core performance. After such unexpected bottlenecks are eliminated, one should generally focus
on scaling efficiency and vectorization in the most time-consuming routines and loops.

We have employed this approach to porting our implementation of the Particle-in-Cell method, gradually profiling, solving performance issues and measuring effect of optimization on CPU and Xeon Phi. Only after our optimization resources on CPU were exhausted, we proceeded to trying Xeon Phi-specific optimizations. Those included manual vectorization using intrinsics translated into vector instructions of Xeon Phi, using large memory pages to reduce DTLB miss rate, non-temporal stores for better cache utilization efficiency, adjusting number of processors and threads in MPI + OpenMP scheme. Most of the enlisted optimization techniques did not yield a significant if any performance benefit for our application, a notable exception is manual vectorization via intrinsics.

4. Porting and Optimization of the Particle-in-Cell Code PICADOR

4.1. PICADOR Particle-in-Cell Code

PICADOR \cite{22,23} is a fully parallel 3D Particle-in-Cell implementation capable of running on heterogeneous cluster systems with CPUs, GPUs and Xeon Phi coprocessors. Features of PICADOR include FDTD and NDF field solvers, Boris particle pusher, CIC and TSC particle form factors, Villasenor-Buneman and Esirkepov current deposition, ionization, moving frame, and dynamic load balancing. Each MPI process handles a part of simulation area (domain) using either a multicore CPU or Xeon Phi coprocessor via OpenMP, or GPU via CUDA. All MPI exchanges occur only between processes handling neighboring domains.

The baseline version was developed taking into account some common knowledge performance considerations, the short description is given below.

Values of each vector component are stored separately in a 3D array wrapped into 1D. Current values are written directly to global current arrays, similarly, field values are read directly from global field arrays. The key performance consideration is a particle storage. We use separate array of particles per each cell with Array-of-Structures (AoS) layout. This approach varies from the widely used global particle array with sorting strategy and is closer to data structures used for GPU-based implementation (but without supercells common for GPUs).

On the most time consuming particle push and current deposition stages particles are processed in a cell-by-cell order. Particles in several cells are processed in parallel using OpenMP in one-pragma style. After each particle push we perform a check and, in case a particle leaves the current cell, update particle storage structure accordingly. This migration check is done partly in parallel: each thread has its own buffer for migrating particles, after all checks are done all buffers are merged and processed sequentially. On the current deposition stage each thread writes to its own current buffer to avoid data races, all buffers are summed after the stage is over.
4.2. Benchmark, Hardware and Performance Measurement Details

For all the performance measurements presented in this paper we used a frozen plasma benchmark with $40 \times 40 \times 40$ grid, 50 particles per cell, and 1000 time steps. We used CIC particle formfactor for field interpolation and current deposition, and perform all calculations in double precision. The time given in tables refers only to the computational phase which is a sum of particle push, current deposition and field update.

Computational experiments were done on a node of Lobachevsky cluster system at University of Nizhni Novgorod with 8-core Intel Sandy Bridge E5-2660 CPUs (2.2 GHz), 64 GB RAM, and 2 Intel Xeon Phi 5110P coprocessors, each with 60 cores, 240 threads, and 8 GB RAM. Peak performance of each CPU in double precision is 140 GFLOPS, and peak performance of Intel Xeon Phi 5110P is 1 TFLOPS. The code was compiled with Intel C++ Compiler.

Table 1 presents performance results of the baseline version on the CPU and Xeon Phi. On Xeon Phi we used native mode and porting required only rebuilding the code and libraries with compiler options for Xeon Phi support (-mmic). Performance on Xeon Phi is very close to CPU, but time distribution between stages is different with faster particle push and significantly slower field update. Thus, no effort port gives reasonable performance (taking in account in only took several hours) but further optimization is required.

Table 1: Performance of the baseline version on CPU and Xeon Phi

| Stage         | Time [s] CPU | Xeon Phi |
|---------------|-------------|----------|
| Particle push | 163.1       | 134.8    |
| Current deposition | 61.3     | 81.3     |
| Field update  | 0.8         | 7.7      |
| Total         | 225.2       | 222.8    |

4.3. Improving Memory Locality

A natural and widely used idea for efficient implementation of the Particle-in-Cell method is to use physical locality of the method — each particle is interacting only with several closest field values — and transform it into memory locality to allow cache-friendly implementation. With CIC particle formfactor and Yee grid particles in each cell interact only with 27 closest grid values for each field and current component (a cube with side 3). Before processing particles of a cell we preload corresponding 27 surrounding field values into a small local array and use these values for field interpolation. In a similar way, we accumulate currents created by particles of a cell in a small local array and add it to the global array after all particles are processed. Thus, we replace the majority of memory operations with global field and current arrays with the same operations on local arrays.
The comparison of performance of this version and the baseline version is presented in Table 2. Improving memory locality yields over 3x benefit over the baseline on both CPU and Xeon Phi.

Table 2: Performance of the version with improved memory locality

| Stage            | Time [s] | Speedup to the baseline |
|------------------|----------|-------------------------|
|                  | CPU      | Xeon Phi                |
| Particle push    | 56.9     | 41.3                    |
|                  | 2.87 x   | 3.26 x                  |
| Current deposition| 14.0   | 16.9                    |
|                  | 4.38 x   | 4.81 x                  |
| Field update     | 0.8      | 7.7                     |
|                  | 1.00 x   | 1.00 x                  |
| Total            | 71.7     | 65.9                    |
|                  | 3.14 x   | 3.38 x                  |

4.4. Enhancing Scalability on Shared Memory

Efficiency of scaling on shared memory is important for multicore CPUs and even more for Xeon Phi. First, we changed parallel current deposition scheme. While storing a separate global current array for each thread to avoid data races is possible for 16 threads it is probably not the most efficient way and definitely not practical for 240 threads of Xeon Phi. Thus, we developed a new parallel current deposition scheme that does not replicate global current array. Again, we employ locality properties described in the previous subsection. Since particles in each cell only contribute to grid values in $3 \times 3 \times 3$ surrounding cube, particles that are distant enough from one another can be processed in parallel without any risk of data races. Namely, for CIC form factor we can concurrently process cells that have 2 unprocessed cells in between; the same idea can be applied to other form factors with probably larger distance. Thus, current deposition consists of 27 particle traversals in checkerboard order, each internal traversal is parallel with only synchronization at the end of the traversal.

Then we eliminated sequential migration of particles between cells. Due to relation between space and time steps, particle can not pass the distance greater than cell size in one time step. Thus, a migrating particle is necessarily located in a neighbor cell. We again applied the checkerboard order parallelization scheme. For each cell we create a buffer for particles migrating to this cell, after pushing a particle each thread computes new cell index and in case of migration writes the particle to a buffer of the new cell. Because of locality and checkerboard traversal order there is not need for synchronization except at the end of each traversal.

The performance of this version is presented in Table 3.

4.5. Improving Vectorization

Efficient vectorization is a key factor in achieving good performance on CPUs and particularly on Xeon Phi coprocessors. The main reason for lackluster performance on Xeon Phi is poor vectorization of the code.
Table 3: Performance of the version with improved memory locality and enhanced scalability

| Stage               | Time [s]       | Speedup to the baseline |
|---------------------|---------------|-------------------------|
|                     | CPU | Xeon Phi | CPU | Xeon Phi |
| Particle push       | 52.1 | 37.1     | 3.13 x | 3.63 x |
| Current deposition  | 13.9 | 13.1     | 4.41 x | 6.21 x |
| Field update        | 0.7  | 1.8      | 1.14 x | 4.28 x |
| Total               | 66.7 | 52.0     | 3.38 x | 4.28 x |

We tried two approaches to vectorization. First we tried to assist the compiler with auto-vectorization by using special directives of Intel Compiler (such as #pragma ivdep and #pragma simd) and loop splitting. It allowed to vectorize implementation of field update and the Boris method for particle push, but did not vectorize more time-consuming field interpolation and current deposition because of complicated memory access pattern. Thus, vectorization lead to a modest speedup of particle push and field update, as shown at Table 4, this version for Xeon Phi is denoted as v1.

Table 4: Performance on CPU and Xeon Phi after improving vectorization. Compiler auto-vectorization version on Xeon Phi is denoted as v1, version with manual vectorization of field interpolation and current deposition is denoted as v2.

| Stage               | Time [s]       | Speedup to the baseline |
|---------------------|---------------|-------------------------|
|                     | CPU | Xeon Phi v1/v2 | CPU | Xeon Phi v1/v2 |
| Particle push       | 45.6 | 20.2 / 18.8 | 3.58 x | 6.67 x / 7.17 x |
| Current deposition  | 13.8 | 13.0 / 10.1 | 4.44 x | 6.25 x / 8.05 x |
| Field update        | 0.6  | 0.8 / 0.8 | 1.33 x | 9.63 x / 9.63 x |
| Total               | 60.0 | 34.0 / 29.7 | 3.75 x | 6.55 x / 7.50 x |

The main reason of lackluster speedup due to vectorization is that for each cell we have to store $3 \times 3 \times 3$ arrays of field and current density components, while each particle uses $2 \times 2 \times 2$ subarray depending on its position inside the cell. The implementation uses indirect indexing which renders vectorization of the loop over particles inefficient on Xeon Phi.

To eliminate indirect indexing the field and current density values have been repacked into eight $2 \times 2 \times 2$ arrays each corresponding to an octant of a cell. Those arrays contain 512-bit vector elements of the components of the electric and magnetic field (6 values) for field interpolation and the components of the current density (3 values) for current deposition. Thus, field interpolation effectively uses 75% of the vector register length and current deposition uses only 37.5%. For each particle we determine the octant it belongs and perform the corresponding operation with vector registers using intrinsics. This modification
was only done for Xeon Phi as vector extensions are different for Xeon Phi and
CPUs and yield additional 1.15x overall speedup, as shown at Table 4.

The main obstacle for efficient vectorization is indirect addressing caused
by usage of the standard Yee grid for values of the electro-magnetic field and
current density [24]. As shown in [21], vectorization can be done much easier
for a more straightforward grid.

5. Performance Evaluation on a Real Simulation

5.1. Problem Statement

In this section we present the results of efficiency measurements of our Xeon
Phi implementation solving a real physical problem. As an example, we chose a
laser ion acceleration in a so-called Target Normal Sheath Acceleration (TNSA)
regime [27]. In this regime ions are accelerated from a rear side of a thin (sub-
micron thick) solid-state target by quasistatic electron sheath. This sheath is
formed by hot electrons accelerated to relativistic energies by laser field at front
surface of the target. One of the main problems of the scheme is its low efficiency
[5]. Recently, it has been suggested to use surface grating on the irradiated size
of the target to increase laser-electron coupling and therefore increase amount
of energy transferred from laser radiation to ions [28]. This proposal has been
tested via a number of 2D numerical simulations [29–31], however for more
realistic results full 3D simulations are needed especially for investigation of
complex gratings. Realistic 3D simulations, however, are known to be extremely
resource-demanding and thus may greatly benefit from the opportunity to be
run on heterogeneous systems enabling resources of Xeon Phi coprocessors.

We investigated irradiation of a 0.3 \( \mu \text{m} \) thick target composed of Au\(^{+31}\)\(^{197}\) ions with plasma density corresponding to electron concentration \(3 \times 10^{21}\ \text{cm}^{-3}\)
(overdense parameter \(n_0 = 30\)). The accelerated proton layer with the same
electron concentration and 0.1 \( \mu \text{m} \) thickness has been attached to a rear side
of the target. The grating in the form of rectangular brush modulated along
y-axis only has been placed on an irradiated side. The grating height has been
chosen to be equal to 0.3 \( \mu \text{m} \), the thickness of a single element was equal to
0.15 \( \mu \text{m} \) and the grating period was equal to 0.5 \( \mu \text{m} \). Initial temperature of
all plasma components was 100 eV which is referred to values usually expected
from collisional heating.

The laser pulse normally impinged on the target was supposed to be an
infinite in transversal direction plane wave propagating along x-axis and linearly
polarized in the y-direction. It had a Gaussian envelope along propagation axis
with duration at full width half maximum equal to 42 fs and its wavelength was
equal to 1 \( \mu \text{m} \). The laser intensity in maximum reached \(3.75 \times 10^{19}\ \text{W/cm}^2\)
(dimensionless amplitude \(a_0 = 5.2\)). These parameters are typical for Ti:Sa
terawatt systems widespread nowadays in laboratories worldwide.

The simulation area is a box of size \(12 \times 1 \times 1\ \text{\mu m}^3\) covered with \(512 \times 64 \times 64\)
grid. A time step was equal to 0.026 fs and the total simulation time was 300 fs,
requiring 11 512 time steps to complete.
The maximal ion energy $W_{\text{max}}$ is sensitive to the number of macroparticles per cell $N_{PPC}$. This is due to the fact that higher $N_{PPC}$ provides better resolution of a tail of sheath electron energy distribution and this tail is known to define the maximal energy $W_{\text{max}}$ reached by the accelerated ions. In our simulations we varied PPC-parameter in 10 to 150 range in order to investigate the dependence of $W_{\text{max}}$ on $N_{PPC}$, which is shown in Fig. 2. One can see that obtained maximal ion energy steadily grows with increasing $N_{PPC}$ until it reaches 14.8 MeV at $N_{PPC} = 80$ and does not grow further. This feature of the investigated problem makes it highly favourable for running on Xeon Phi coprocessors because in comparison with CPUs they do Particle-in-Cell simulations with high $N_{PPC}$ faster.

5.2. Performance Evaluation

We measured performance of simulations on 2 CPUs and 2 Xeon Phi coprocessors with the number of particles per cell varying from 10 to 80. The results are presented in Fig. 3. Three most time-consuming stages are particle push, current deposition and MPI exchanges. Other stages, including field solver, pulse generation and absorbing boundary conditions took negligible time.

MPI communication phase on Xeon Phi takes much longer not only due to additional data transfer between coprocessor and host occurring with each MPI data exchange, but mainly due to preparation of the data to be transferred involving copying of the boundary of 3D arrays to 1D arrays, that is not fully parallelized. Total computational time on CPU and Xeon Phi is close for $N_{PPC} = 10$ with Xeon Phi steadily outperforming CPU as $N_{PPC}$ grows. For $N_{PPC} = 80$ simulation on Xeon Phi is 1.6x times faster compared to CPU with 2.8x speedup of particle push, 2.0x speedup of current deposition, 2.6x
Figure 3: Performance of 2x CPUs and 2x Xeon Phi coprocessors on a TNSA simulation with 10 to 80 macroparticles per cell.

overall speedup of computational core, and significantly slower data exchanges and related operations.

6. Summary

This paper studies suitability of Intel Xeon Phi coprocessors as accelerators for Particle-in-Cell plasma simulation. We discuss features of Xeon Phi that influence performance of Particle-in-Cell implementations. Limitation of 16 GB RAM on Xeon Phi is not a severe constraint for Particle-in-Cell simulation. Due to massive parallelism potential of the Particle-in-Cell method it can efficiently utilize Xeon Phi. We found that an important limiting factor is low single-core performance, particularly for code that is not ideally vectorized. In practice, it means that the pieces of code fast enough to not be parallelized or vectorized on CPU can become a bottleneck on Xeon Phi and therefore has to be rewritten.

We confirm this conclusions by porting of an existing 3D Particle-in-Cell plasma simulation code PICADOR to Xeon Phi coprocessors. The parallel C++ code using MPI and OpenMP was originally ported by means of just recompiling with performance on Xeon Phi close to that of 8-core CPU. We demonstrate step-by-step application of standard optimization techniques: improving memory locality, scaling efficiency and vectorization that lead to overall speedup of 3.75x on CPU and 7.5x on Xeon Phi. On a test problem with 50 macroparticles per cell the final version achieves 18.8 ns per particle update on CPU and 9.3 ns per particle update on Xeon Phi in double precision. On the
real simulation of laser ion acceleration two Xeon Phi coprocessors outperform two CPUs by factor of 1.6. Our implementation demonstrates good scaling on shared memory with 240 threads of Xeon Phi. The most challenging aspect of efficient implementation is vectorization of field interpolation and vectorization due to non-unit stride memory access. Overall, the Particle-in-Cell method, although not ideally suited for Xeon Phi coprocessors due to vectorization issues, allows to achieve significant performance gain on a modern heterogeneous clusters.

In terms of further development, the second-generation Intel Knights Landing coprocessors has significant advances over the current Xeon Phi architecture including significant improvement of the single-core performance and support for out-of-order execution, and capability for direct data exchanges between coprocessors avoiding PCI Express. Higher single-core performance will allow efficient Particle-in-Cell simulation with lower number of macroparticles per cell and to a certain extent alleviate performance degradation of a poorly vectorized or parallelized code. The capability for coprocessor-only simulation with direct data transfers provides good scaling potential. This improvements together with our good experience of porting PICADOR to existing hardware makes Xeon Phi coprocessors a very promising hardware platform for high-performance Particle-in-Cell plasma simulation.

This study was partially supported by the RFBR, research project No. 14-07-31211 and by the grant (the agreement of August 27, 2013 No. 02..49.21.0003 between The Ministry of education and science of the Russian Federation and Lobachevsky State University of Nizhni Novgorod).
