(Dated: January 17, 2020)

We study the localization properties of the two-dimensional Lieb lattice and its extensions in the presence of disorder using transfer matrix method and finite-size scaling. We find that all states in the Lieb lattice and its extensions are localized for \( W \geq 1 \). Clear differences in the localization properties between disordered flat band and disordered dispersive bands are identified. Our results complement previous experimental studies of clean photonic Lieb lattices and provide information about their stability with respect to disorder.

I. INTRODUCTION

It is a matter of university physics to show that quantum descriptions of crystalline systems can be carried out equally well in real space as in momentum space [9–12]. In perfect crystals, the momentum space description offers the advantage that all spatial information is already encapsulated in the unit cell, hence allowing for a dramatic reduction in the complexity of describing such materials. The structure of the resulting energy bands, their number, curvature, linearity, filling and behaviour at the Fermi energy are all important descriptors, essential for the determination of the material properties of said systems. In recent years, e.g., interest has broadened this approach towards a description of the topological properties of the bands [3, 4] with concepts such as Fermi arcs [5, 6] and Weyl points [7] indicating highly-specialized band structure features.

In a similar context, so called flat bands have also received much attention [8]. The term refers to energy bands that are dispersionless in the whole of \( k \)-space [9–12]. This is equivalent to effectively having zero kinetic energy in these bands and hence to promoting the remaining terms in the Hamiltonian such as potential and interaction terms. Usually, such flat band emerge only for specially “engineered” lattice structures such as quasi-1D lattices [13–15], diamond-type lattices [16], and Lieb lattices [17–22]. Such Lieb lattices were originally used to enhance magnetic effects in model studies [9, 23] but have now been shown to be of experimental relevance in Wigner crystals [22], high-temperature superconductivity [11, 18], photonic wave guide arrays [8, 24–27], Bose-Einstein condensates [28, 29], ultra-cold atoms in optical lattices [30] and electronic systems [31].

The eigenstates in a flat band lattice are known to form so-called compact localized states [13], which due to the effectively zero group velocity, cannot participate in transport although they are in principle infinitely degenerate [10]. Since the existence of flat bands relies on exact conditions, weak deviations from these conditions, such as potential disorder, could in principle fundamentally alter the nature of these localized states. Indeed, previous studies reveal a wide spread of tendencies depending on the nature of the perturbations [13, 15, 22, 23] as well as the environment of the bands [30, 31]. Our focus here is slightly different: instead of concentrating on the localization properties of the flat band states, we will investigate how the localization properties in the neighboring dispersive band are changed by the presence of the flat bands. In particular, we are interested in whether the presence of the flat bands changes the localization properties and the finite-size scaling behaviour in disordered two-dimensional (2D) Lieb model and its extensions.

II. MODELS AND METHOD

A. The Lieb lattices \( \mathcal{L}(n) \)

The original Lieb lattice [23] is based on a square lattice with additional sites added along the horizontal and vertical directions as shown in Fig. 1. We denote the original sites as A while B and C denote the added horizontal and vertical sites, respectively. In Ref. 40, extended Lieb lattices have been proposed with additional added sites as also shown in Fig. 1. We shall denote all these lattices symbolically as \( \mathcal{L}(n) \) with \( n \) denoting the number of sites added in both horizontal and vertical directions, i.e. here \( \mathcal{L}(1) \) to \( \mathcal{L}(4) \). Our numerical approach to study the localization properties of the Lieb lattices \( \mathcal{L}(n) \) is based on (i) direct diagonalization of the Hamiltonian for small system sizes, and (ii) the transfer matrix method (TMM) [31, 42]. TMM has been used extensively for various disorder problems [43, 44] and is the currently accepted method-of-choice for high-precision estimates of parameter-dependent localization lengths [15].

We start with the standard Anderson tight-binding
Hamiltonian
\[
H = \sum_{\vec{r}} \varepsilon_{\vec{r}} |\vec{r}\rangle \langle \vec{r}| - \sum_{\langle \vec{r}, \vec{r}' \rangle} t_{\vec{r}, \vec{r}'} |\vec{r}\rangle \langle \vec{r}'|,
\]
where $|\vec{r}\rangle$ denotes the tight-binding state site $\vec{r} = (x, y)$, $x$ and $y$ indicate the exact position in the 2D plane and $\langle \vec{r}, \vec{r}' \rangle$ indicates the nearest-neighbor connections as defined in Fig. 1. The onsite potential energy $\varepsilon_{\vec{r}}$ at site $\vec{r}$ is randomly and uniformly distributed in $[-W/2, W/2]$ such that $W$ indicates the strength of the disorder. The $t_{\vec{r}, \vec{r}'}$ are the hopping integrals for a particle going from site $\vec{r}$ to site $\vec{r}'$, and represent the kinetic energy part of the Hamiltonian. We only set nearest neighbours hopping in our model, so that $t_{\vec{r}, \vec{r}'} = t \equiv 1$ for nearest sites sets the energy scale and $t_{\vec{r}, \vec{r}'} = 0$ otherwise.

**B. Transfer-matrix method for $\mathcal{L}(1)$**

For the $\mathcal{L}(1)$ lattice, in order to compute the localization length $\lambda$ of the wave function from the TMM corresponding to the Schrödinger equation $H \Psi = E \Psi$, we consider a quasi-1D strip consisting of $M$ chains of $A$ and $B$ atoms with additional $M$ C sites in the vertical ($y$-) direction and propagate the TMM in the horizontal ($x$-) direction until convergence. This implies a TMM setup with two transfer matrices, namely from sites A to B in $y$-direction, we find

\[
\begin{pmatrix}
\psi^B_{x+1,y} \\
\psi^A_{x,y}
\end{pmatrix}
= T_{A \rightarrow B}
\begin{pmatrix}
\psi^A_{x,y} \\
\psi^B_{x-1,y}
\end{pmatrix}
= \begin{pmatrix}
\frac{\varepsilon_{x,y} - E}{t} - \frac{t}{\varepsilon_{x+1,y} - E} & -\frac{t}{\varepsilon_{x,y+1} - E} & -1_M \\
\frac{t}{\varepsilon_{x,y+1} - E} & \frac{\varepsilon_{x,y+1} - E}{t} & 0_M
\end{pmatrix}
\begin{pmatrix}
\psi^A_{x,y} \\
1_M \\
\psi^B_{x-1,y}
\end{pmatrix}
\]

emerges as
\[
\begin{pmatrix}
\psi^A_{x+1,y} \\
\psi^B_{x,y}
\end{pmatrix}
= T_{B \rightarrow A}
\begin{pmatrix}
\psi^A_{x,y} \\
\psi^B_{x-1,y}
\end{pmatrix}
= \begin{pmatrix}
\frac{\varepsilon_{x,y} - E}{t} & -1_M \\
1_M & 0_M
\end{pmatrix}
\begin{pmatrix}
\psi^A_{x,y} \\
\psi^B_{x-1,y}
\end{pmatrix}
\]

The transfer matrices $T_{B \rightarrow A}$ and $T_{A \rightarrow B}$ transfer the wave vector amplitudes $\Psi$ between atoms A and B. Along the transfer ($x$-) axis, we multiply these matrices, re-orthogonalize the $M$ $\Psi$ states, i.e. the columns of the TMM, at least after every 10th multiplication, compute Lyapunov exponents $\gamma_i$, $i = 1, \ldots, M$ and study their accumulated changes in variance until we reach a desired accuracy (typically of 0.1%) for the smallest $\gamma_{\text{min}}$ [42, 46–48]. The localization length is then found as

**FIG. 1.** Schematic structure of lattices $\mathcal{L}(1)$, $\mathcal{L}(2)$, $\mathcal{L}(3)$ and $\mathcal{L}(4)$, respectively. Circles denote the lattice sites with blue/dark circles corresponding to the sites of a simple square lattice and the red/light circles denoting the added sites of the Lieb lattices. The thin black lines between the sites indicate hopping connections. A, B, \ldots, E give special labels used in the explanation of the TMM in the text. The $x$ and $y$ axes are denoted by arrows.
\[ \lambda(M, W, E) = 1/\gamma_{\text{min}} \] for given energy \( E \) and disorder strength \( W \).

C. TMM for \( \mathcal{L}(2) \) and beyond

For the extended Lieb lattice \( \mathcal{L}(2) \), we can derive the corresponding TMM recursion formulae in a similar fashion.

\[
\begin{pmatrix}
\Psi_{x+1,y}^C \\
\Psi_{x,y}^A \\
\Psi_{x,y}^B \\
\Psi_{x-1,y}^C \\
\end{pmatrix} = T_{A \rightarrow C}
\begin{pmatrix}
\Psi_{x,y}^A \\
\Psi_{x-1,y}^B \\
\end{pmatrix}
\]

\[
= \begin{pmatrix}
\frac{\epsilon_{x,y} - E}{t} & 0 & 0 & -\frac{t}{\epsilon_{x,y} - E} \\
0 & \frac{\epsilon_{x,y} - E}{t} & 0 & -\frac{t}{\epsilon_{x,y} - E} \\
0 & 0 & \frac{\epsilon_{x,y} - E}{t} & 0 \\
-\frac{t}{\epsilon_{x,y} - E} & 0 & 0 & \frac{\epsilon_{x,y} - E}{t} \\
\end{pmatrix}
\begin{pmatrix}
\Psi_{x,y}^A \\
\Psi_{x-1,y}^B \\
\Psi_{x,y}^C \\
\Psi_{x-1,y}^C \\
\end{pmatrix}.
\]

while from sites \( C \rightarrow B \), we have

\[
\begin{pmatrix}
\Psi_{x+1,y}^B \\
\Psi_{x,y}^C \\
\Psi_{x,y}^A \\
\Psi_{x-1,y}^C \\
\end{pmatrix} = T_{C \rightarrow B}
\begin{pmatrix}
\Psi_{x,y}^A \\
\Psi_{x-1,y}^C \\
\end{pmatrix}
\]

\[
= \begin{pmatrix}
\frac{\epsilon_{x,y} - E}{t} & 0 & 0 & -\frac{t}{\epsilon_{x,y} - E} \\
0 & \frac{\epsilon_{x,y} - E}{t} & 0 & -\frac{t}{\epsilon_{x,y} - E} \\
0 & 0 & \frac{\epsilon_{x,y} - E}{t} & 0 \\
-\frac{t}{\epsilon_{x,y} - E} & 0 & 0 & \frac{\epsilon_{x,y} - E}{t} \\
\end{pmatrix}
\begin{pmatrix}
\Psi_{x,y}^A \\
\Psi_{x-1,y}^C \\
\Psi_{x,y}^C \\
\Psi_{x-1,y}^C \\
\end{pmatrix}.
\]

and for \( B \rightarrow A \)

\[
\begin{pmatrix}
\Psi_{x+1,y}^B \\
\Psi_{x,y}^C \\
\Psi_{x,y}^A \\
\Psi_{x-1,y}^C \\
\end{pmatrix} = T_{B \rightarrow A}
\begin{pmatrix}
\Psi_{x,y}^B \\
\Psi_{x-1,y}^C \\
\end{pmatrix}
\]

\[
= \begin{pmatrix}
\frac{\epsilon_{x,y} - E}{t} & 0 & 0 & -\frac{t}{\epsilon_{x,y} - E} \\
0 & \frac{\epsilon_{x,y} - E}{t} & 0 & -\frac{t}{\epsilon_{x,y} - E} \\
0 & 0 & \frac{\epsilon_{x,y} - E}{t} & 0 \\
-\frac{t}{\epsilon_{x,y} - E} & 0 & 0 & \frac{\epsilon_{x,y} - E}{t} \\
\end{pmatrix}
\begin{pmatrix}
\Psi_{x,y}^B \\
\Psi_{x-1,y}^C \\
\Psi_{x,y}^C \\
\Psi_{x-1,y}^C \\
\end{pmatrix}.
\]

As before, the hopping in vertical (\( y \)-) direction has been included in renormalization of the onsite energies of the \( A \) sites as well as a renormalized hopping between \( A \) sites, albeit more complicated in structure than for \( \mathcal{L}(1) \). Still, following this procedure, it is not difficult to construct the transfer matrices for the remaining \( \mathcal{L}(3) \) and \( \mathcal{L}(4) \) lattices and we will not include those even lengthier terms here.

D. Finite-size scaling in 2D

According to renormalization group ideas \[49\], we can study the properties of large systems from smaller sub-systems \[50\]–\[52\]. We define the dimensionless, reduced localization length \( \Lambda_M(E, W) = \lambda(E, W)/M \). In order to get the infinite-size localization length \( \xi \) \[53\] from the localization. Starting again from the first sites in \( x \)-direction as given in Fig. \ref{fig:1} for \( \mathcal{L}(2) \), we find for the transfer from sites \( A \rightarrow C \),

\[
\Lambda_M(E, W), \text{ we should apply the one-parameter-scaling hypothesis, i.e.}
\]

\[
\Lambda_M(E, W) = f(\xi(E, W)/M).
\]

As a numerical procedure, this means that the finite size \( \Lambda_M \) values can be scaled by a factor \( \xi \), such that all values collapse onto a single scaling function \( f \). We fit the parameter \( \xi \) by using a least squares procedure \[41\] either as a function of \( E \) for constant \( W \), or, more standard, as a function of \( W \) for constant \( E \). We then determine the absolute scale of \( \xi(W, E) \) by fitting the largest disorder with the form of a truly localised behaviour, i.e.

\[
\Lambda_M = \xi/M + b(\xi/M)^2,
\]

as expected for large \( W \gg t \). We emphasize that numerically, this procedure does not use the Taylor expansion methods nor does it assume any power-law diverging terms as is normally standard in studies of the 3D Anderson transition and its variants \[45\]–\[53\]. Rather, as there is no transition in 2D, there is no universal functional form to fit towards \[41\] and we hence have to revert back to the simpler methods of maximizing data overlap as done in most pre-1999 studies of Anderson localization \[42\].

III. RESULTS

A. Dispersion relations and disorder-broadened density of states for \( \mathcal{L}(n) \)

In the clean lattice \( \mathcal{L}(1) \), we can easily compute the dispersion relations from the tight-binding model \[1\] as

\[
E_1 = 0, \quad E_{2,3} = \pm \sqrt{4 + 2(\cos k_x + \cos k_y)}
\]

(9)
FIG. 2. The band structure (top row) and the smoothed and normalized density of states (DOS, bottom row) for \( \mathcal{L}(1) \) with width \( M = 13 \), \( \mathcal{L}(2) \) with \( M = 10 \), \( \mathcal{L}(3) \) with \( M = 9 \) and \( \mathcal{L}(4) \) with \( M = 8 \). Colours in the top row vary from purple at low energies to red at high energies. In the bottom row, the colour indicates the numerical values of the DOS and the thin black lines are equal-DOS contours.

where we have chosen the unit length to be 1, and the \( k_x, k_y \) are the wave vectors mapping onto the \( x \) and \( y \) axes. Fig. 2 plots the \( \mathcal{L}(1) \) band structure and we can clearly see the flat band at energy \( E = 0 \), and a Dirac cone around the ‘\( M \)’ point \((k_x, k_y) = (\pi, \pi)\). Similarly, we compute the band structures for \( \mathcal{L}(n) \), \( n = 2, 3, 4 \) and show them in the last three plots in Fig. 2. We see that every \( \mathcal{L}(n) \) exhibits \( n \) flat bands separated by \( n + 1 \) dispersive bands [40]. Furthermore, the odd \( n = 1, 3 \) lattices show Dirac cone at special points in the \((k_x, k_y)\) plane while the even \( n = 2, 4 \) lattices only seem to have parabolic-type dispersions.

We now turn on the disorder, i.e. \( W > 0 \). Obviously, \( k_x \) and \( k_y \) are no longer good quantum numbers and the dispersion relations loose their meaning. Nevertheless, as discussed previously, the flat bands correspond to zero kinetic energy are dominated by the remaining term in the Hamiltonian, i.e. the random disorder term. Hence already small \( W \) values can quickly lift the degeneracy of the flat bands and the states can begin the overlap with states in the originally dispersive, neighboring bands. In order to study the interplay of flat bands and dispersive bands in the disordered situation, we have computed the disorder-dependence of the density of states (DOS) by exact diagonalization for small system sizes \( M^2 = 13^2, 10^2, 9^2 \) and \( 8^2 \) for \( \mathcal{L}(1) \), \( \mathcal{L}(2) \), \( \mathcal{L}(3) \) and \( \mathcal{L}(4) \), respectively. The DOS has been obtained after averaging over 300 samples, again. The results are given in Fig. 2. Clearly, the figure shows that in all cases the degeneracy of the flat bands is lifted very quickly and the originally degenerate states rapidly begin to move into energy regions occupied by the dispersive bands. Similarly, but somewhat less pronounced, the flat regions of the dispersive bands vanish upon increasing \( W \). Overall, when \( W \) becomes of the order of 2–3, comparable to the band width of the largest subband in each case, the DOS looses it peak features.

B. Localization and finite-size scaling

In Fig. 3 we give the result of the TMM calculations for \( \Lambda_M(E, W) \) at \( E = 0 \). The system sizes were \( M = 10, 12, \ldots, 20 \) with accuracy of 0.1\% for \( \mathcal{L}(1) \), and \( M = 10, 12, \ldots, 22 \) with accuracy 0.2\% for \( \mathcal{L}(2) \), \( \mathcal{L}(3) \) and \( \mathcal{L}(4) \). This results in about \( 10^8 \) transfer matrix multiplications for each pair \((E, W)\). We have chosen \( E = 0 \) since this corresponds to the flat bands for \( \mathcal{L}(1) \) and \( \mathcal{L}(3) \) while it is in the centre of the subbands for \( \mathcal{L}(2) \) and \( \mathcal{L}(4) \). Hence \( E = 0 \) allows us to study directly the influence of the disorder on originally flat and on originally dispersive bands. We find that in all cases, irrespective of the flatness of the original clean lattice bands, the values of \( \Lambda_M(E,0) \) reduce for all values of \( W \) when increasing \( M \) as shown in the inset of Fig. 3. This is the behaviour as expected for localized states where for sufficiently large \( W \) and \( M \), the values of \( \lambda_M \) decrease when \( M \) increases. Indeed, in the main panels of Fig. 3 we see that all \( \Lambda_M(0, W) \) data can be made to scale onto single scaling curves. These curves also decrease with increasing \( M \), hence showing strong localization. Furthermore, for \( \lambda_M \ll M \) such that \( \Lambda_M \ll 1 \), we find that \( \Lambda_M \propto 1/M \) as expected for strong localization with \( \lambda_M \sim \lambda_\infty \). We also note immediately that the localization lengths for the states originating from flat bands are nearly one order of magnitude smaller than the cor-
FIG. 3. Double logarithmic plot of scaled reduced localization length, $\Lambda_M$, as a function of $\xi/M$ for $L(1)$, $L(2)$, $L(3)$ and $L(4)$ as indicated. The chosen values for $W$ are $1.0$ (♦), $1.01$, $1.05$ (□), $2.0$, $2.1$, $2.2$, $2.4$, $2.6$, $10.0$ (○) and vary in color. Some data points are not shown with symbols for clarity. Error bars are within symbol size. Insets: $\Lambda_M$ as a function of $1/M$ for each $L(n)$, respectively. Symbols and colors are as in the main panels, dashed lines are guides to the eye only.

responding $\Lambda_M(0,W)$ values for the originally dispersive bands. Hence, in perfect agreement with our aforementioned expectations, we see that the absence of kinetic energy in the flat bands for the clean systems translates into strong localization for the disordered systems.

In Fig. 4 we show the resulting $W$ dependence of the scaling lengths $\xi(0,W)$. According to Thouless [41, 55], we expect $\xi(W) \propto W^{-2}$ for a strictly 1D weakly disordered chain while in the 2D Anderson model the low $W$ behaviour has been shown to follow a non-universal $\xi(W) = aW^{-\alpha}\exp(\beta W^{-\gamma})$ with $a$, $\beta$ positive and $\alpha, \gamma$ of order unity [42]. These fits are also given in Fig. 4 and the resulting fit parameters are listed in Table I. As is clear from Fig. 4, the behaviour for $L(1)$ and $L(3)$, i.e. the flat bands, is clearly different from the behaviour of the dispersive bands for $L(2)$ and $L(4)$. This is already visible in the absolute magnitude of the $\xi$ values where the $L(1)$ and $L(3)$ cases are about three order of magnitude below the values for $L(2)$ and $L(4)$ for low $W$. For $L(1)$ and $L(3)$, the simple power-law fit $\xi(W) \propto W^{-2}$ seems to work reasonably well at $1 \leq W \leq 2$ while at $W > 2$, in both cases the estimated $\xi$ values drop below the fit. One might want to speculate that this apparent consistency with a 1D fit result might also indicate that the spatial localization itself is along 1D structures, but this is clearly beyond what TMM can reliably infer. We also note that the agreement with the $\alpha = 2$ value in 1D localization is not perfect while the value of $a$ should be $105$ at $E = 0$ [56] for 1D and about $12M$ for quasi-1D stripes of width $M$ [57]. Clearly, none of these values are obvious from the fit parameters given in Table I. On the other hand, for $L(2)$ and $L(4)$, none of our fits as given in Table I seem very convincing with the non-universal 2D behavior perhaps performing slightly better. Of course the lack of a simple fit to the low-$W$ behaviour of $\xi$ is not surprising and simply indicates that the disordered Lieb models $L(n)$ have indeed different localization behaviour than the standard 2D Anderson model.

IV. CONCLUSIONS

We have studied the localization properties of the disordered 2D Lieb lattice and its extensions. After appropriately finite-size scaling, we find that all states are localized, down to numerically accessible disorders of $W \sim 1$. Our results indicate that the finite-size scaled localization lengths $\xi$ for the energies corresponding the
and flat bands in the clean system \((W = 0)\) show a behaviour
to perturbative result for 1D. This could poten-
tially provide spatial information about the nature
of these localized states. For energies corresponding to
dispersive bands in the clean system there is tendency
towards much larger localization lengths as is expected
from the 2D Anderson model of localization \[53\]. Hence,
the clear differences observed between flat and dispersive
bands in photonic Lieb lattices \[40\] are predicted to be
largely robust against the presence of disorder.

ernment (R.A.R.) for financial support.

**Appendix A: Expressions for the dispersion relations**

For completeness, we give the dispersion relations for
the Lieb lattices \(\mathcal{L}(2), \mathcal{L}(3)\) and \(\mathcal{L}(4)\) here. For \(\mathcal{L}(2)\), we find

\[
E_{1,2} = \pm 1, \quad E_3 = \rho_+ + \rho_- \quad (A1a)
\]

\[
E_4 = \omega \rho_+ + \omega^2 \rho_-, \quad E_5 = \omega \rho_- + \omega^2 \rho_+ \quad (A1b)
\]

where the \(\omega = \frac{-1 + \sqrt{3}}{2}\), \(\rho_\pm = \sqrt{q \pm \sqrt{q^2 - \left(\frac{1}{2}\right)^2}}\) and \(q =
\cos k_x + \cos k_y\). For \(\mathcal{L}(3)\),

\[
E_1 = 0, \quad E_{2,3} = \pm \sqrt{2}, \quad (A2a)
\]

\[
E_{4,5,6,7} = \pm \sqrt{3 \pm 5 + 2 (\cos k_x + \cos k_y)} \quad (A2b)
\]

For \(\mathcal{L}(4)\), the flat band solutions are given by

\[
E_{1,2,3,4} = \frac{1}{2} \pm 1 \pm \sqrt{5} \quad (A3a)
\]

The remaining 5 dispersive bands emerge as solutions to
a 5th order equation, i.e.

\[
E^5 - 7E^3 + 9E - 2 (\cos k_x + \cos k_y) = 0 \quad (A3b)
\]

which we solve numerically.
