Regulation Control in Interpreted Petri Nets Under Partial Observation

Italia Jiménez-Ochoa∗ Daniel Guevara-Lozano∗ C. Renato Vázquez** Antonio Ramírez-Treviño∗

Abstract: This paper addresses the regulation control problem for discrete event systems (DES) under partial information. In this approach, the system to be controlled, named the plant, and the required behavior, named the specification, are both represented as Petri nets (PNs) with input and output symbols. The goal is to synthesize a controller that indicates input symbols to the plant in order to reach a state where the output is equal to that of the specification. To achieve this goal, the only information available to the controller is the plant output, i.e., the controller does not know the exact state of the plant. In this work, a control methodology is proposed to synthesize regulation controllers under this setting.

Keywords: Petri nets, Event-based control, Supervisory-control.

1. INTRODUCTION

The control of discrete event systems (DES) has been widely studied in the last decades (Wonham et al. (2018); Giua and Silva (2018)). The most studied control approach for DES is the Supervisory Control theory (Ramadge and Wonham (1982, 1987); Moody and Antsaklis (1998)), initially proposed for finite state automata and later extended to Petri nets (PNs), in which the specification is a language that describes all the event-sequences that are allowed in the closed-loop system. In this framework, the supervisor disables key events in order to constrain the system behaviour into the specification language. The Generalized Mutual Exclusions approach (Giua et al. (1992); Basile et al. (2013)) is another well-known control strategy designed for PNs, in which bounds on the weighted sum of tokens of particular places are imposed to avoid unsafe or deadlock states. This technique has been extensively studied for liveness-enforcing of particular classes of PNs (Chen et al. (2011); Li et al. (2012)).

The regulation control approach was introduced in SanPROTOY et al. (2001); Sánchez-Blanco et al. (2004) in order to develop efficient and intuitive controllers for DES, in which the goal is to drive the system to states where some required output sensors are activated. The regulation framework has been recently revisited for its application in industrial automation systems by Vázquez et al. (2018); Guevara-Lozano et al. (2019). In this framework, the system to be controlled, named the plant, is represented by a PN where input symbols are associated to transitions and output symbols are associated to places, representing actuators and sensors, respectively. Similarly, the required behavior is also represented as a PN, named specification, where the input symbols describe guards and the output symbols describe the output signals required from the plant. The regulation control problem consists in the synthesis of an external agent (controller) that provides input symbols to the plant to reach a state where the plant output is equal to the specification output.

The control regulation problem is related to the Supervisory Control. However, there are relevant differences. In the regulation framework, the user does not specify neither a required language nor required states. Instead, the user specifies sequences of required input/output symbols as a PN (i.e., activation of sensors/actuators). The controller synthesis does involve the computation of particular states and event-sequences to fulfill the specification, but this process can be fully automatized. Moreover, rather than enclosing the plant behavior, the regulation control enforces the computed event-sequences. The advantage of this approach is that the user does not require neither a deep knowledge of the plant nor a training on DES theory to describe a specification. Moreover, the practical complexity can be dramatically reduced.

In this work, it is assumed that the activation of the plant output symbols is the only information available to the controller, then there exist several possible plant markings for the same sensor signals combination. The contribution of this work is to propose an approach to deal with this issue, in this, one controller is designed for each possible initial marking, and a dynamic mechanism is proposed in order to select a controller that drives the plant to a convenient marking without enabling unplanned sequences.

* This work has been supported by program SNI Conacyt. The research leading to these results has received support from the Conacyt Fondo Sectorial de Investigación para la Educación, project number 288470.
This paper is organized as follows. Basic definitions are provided in Section 2. Section 3 describes the regulation control problem. The synthesis of a controller is introduced in Section 4 for the case in which the plant state is available to the controller. The case in which only the plant output is available is addressed in Section 5. Finally, some conclusions and future work are provided in Section 6.

2. DEFINITIONS

In the sequel, the $i$-th column (resp. row) of a matrix $A$ is denoted as $A(\bullet, i)$ (resp. $A(i, \bullet)$). Given sets of indexes $S_r$ and $S_c$, $A(S_r, S_c)$ denotes the sub-matrix built with the entries of $A$ at the rows and columns indicated by $S_r$ and $S_c$, respectively.

Definition 2.1. A PN structure is a bipartite digraph represented by the 4-tuple $G = (P, T, I, O)$, where $P = \{p_1, p_2, ..., p_n\}$ is the finite set of places, $T = \{t_1, t_2, ..., t_m\}$ is the finite set of transitions, $I : P \times T \to \mathbb{N}$ is a function representing the weighted arcs going from places to transitions, and $O : T \times P \to \mathbb{N}$ is a function representing the weighted arcs going from transitions to places, $\mathbb{N}$ is the set of nonnegative integers. Graphically, places are represented by circles, transitions by rectangles and arcs by arrows. The incidence matrix of $G$ is defined as $C = [c_{ij}]$, where $c_{ij} = O(t_j, p_i) - I(p_i, t_j)$. See Silva (1993); David and Alla (2010) for further information about PNs.

As usual, $t_j$ (resp. $p_i$) denotes the set of all places $p_i$ (resp. transitions $t_j$) such that $I(p_i, t_j) \neq 0$ (resp. $O(p_i, t_j) \neq 0$). Similarly, $p^c_j$ (resp. $t^c_j$) denotes the set of all places $p_i$ (resp. transitions $t_j$) such that $O(p_i, t_j) \neq 0$ (resp. $I(p_i, t_j) \neq 0$). A PN is a state machine if each transition has only one input and one output place, i.e., $\forall t \in T, |t| = |t^c| = 1$ and the Petri net graph is strongly connected. The marking function $M : P \to \mathbb{N}$ is a mapping representing the number of tokens residing into each place. The marking of a PN is expressed as an $n$-entry column vector $M$. Graphically, tokens are represented as dots inside places.

Definition 2.2. A PN system is the pair $\langle G, M_0 \rangle$, where $G$ is a PN structure and $M_0$ is an initial token distribution. A transition $t_j$ is enabled at marking $M_k$ if $\forall p_i \in t_j, M_k(p_i) \geq I(p_i, t_j)$, this is denoted as $M_k \xrightarrow{t_j}$. A transition $t_j$ can fire (the corresponding event can occur) if it is enabled, in such case, the system reaches a new marking $M_{k+1}$ that can be computed with the so-called PN fundamental equation $M_{k+1} = M_k + Cv_k$, where $v_k(i) = 0$ for $i \neq j$ and $v_k(j) = 1$. This is denoted as $M_k \xrightarrow{t_j} M_{k+1}$.

Definition 2.3. A firing sequence of a PN $\langle G, M_0 \rangle$ is a sequence of transitions $\sigma = t_{i_1}t_{i_2}...t_{i_k}$ such that $M_0 \xrightarrow{t_{i_1}} M_1 \xrightarrow{t_{i_2}} ... \xrightarrow{t_{i_k}} M_k$. The Parikh vector $\sigma$ of a firing sequence $\sigma$ is defined as a column vector of length $|T|$ such that $\sigma(j) = k$ if $t_j$ is fired $k$ times in the sequence $\sigma$. In this way, the marking $M'$ reached after the firing of $\sigma$ from a marking $M$ can be computed with the fundamental equation

$$M' = M + C\sigma$$

This is denoted as $M \xrightarrow{\sigma} M'$, $\sigma$ is said to be fireable from $M$ and $M'$ is said to be reachable from $M$.

The reachability set of a PN is the set of all the reachable markings from $M_0$, and it is denoted as $R(G, M_0)$. A PN system is said safe if $\forall M \in R(G, M_0)$ and $\forall p \in P$ it holds $M(p) \leq 1$. A vector $b \neq 0$ such that $b^T C = 0$ is said to be a P-flow. The matrix $B_p$ denotes a basis for the P-flows of the net. Nonnegative P-flows are called P-semiflows. Every reachable marking $M' \in R(G, M_0)$ satisfies $b^T M = b^T M_0$. In this work, it will be assumed that all the P-flows are initially marked, thus $b^T M_0 > 0$.

Definition 2.4. (Ramírez-Trevino et al. (2003)). An Interpreted Petri Net (IPN) system is a 5-tuple $Q = \langle G, M_0, \Sigma_I, \lambda, \varphi \rangle$ that models the discrete event system to be controlled.

• $(G, M_0)$ is a PN system;
• $\Sigma_I$ is the input alphabet of the PN system, where each element of the set $\Sigma_I$ is an input symbol;
• $\lambda : T \to \Sigma_I \cup \{\epsilon\}$ is the labeling function of transitions with the restriction that nondeterministic inputs are not allowed, i.e., $\forall t_j, t_k \in T, j \neq k$, if $I(p_i, t_j) = I(p_i, t_k) \neq 0$ and both $\lambda(t_j), \lambda(t_k) \neq \epsilon$, then $\lambda(t_j) \neq \lambda(t_k)$ Here, $\epsilon$ represents a system’s internal event;
• $\varphi$ is an $n \times n$ matrix whose entries belong to $\{0, 1\}$, where $n$ is the number of outputs and $n$ is the number of places. The IPN output vector at marking $M_k$ is defined as $y_k = \varphi \cdot M_k$.

In this work it is assumed that each place is associated to at most one distinct output, i.e. $\varphi(i, \bullet) \cdot \varphi(\bullet, i)$ are elementary vectors. If $\lambda(t_j) \neq \epsilon$, the transition $t_j$ is said to be controllable. Otherwise, it is uncontrollable. The set of uncontrollable transitions is denoted as $T_u$. A place $p_i \in P$ is said to be measurable if the $j-th$ column of $\varphi$ is not null. i.e. $\varphi(\bullet, j) \neq 0$. Otherwise, it is nonmeasurable.

The evolution of an IPN is similar to that of the PN system, where the following aspects are also considered for the transitions firing.

• The input symbols are said to be indicated when an external controller requires the firing of the corresponding transitions. If $\lambda(t_j) = \alpha$, $\neq \epsilon$ is indicated and $t_j$ is enabled then $t_j$ must fire. If $t_j$ is enabled by the marking, but the symbol $\lambda(t_j)$ is not indicated, then $t_j$ cannot fire. If $\lambda(t_j) \neq \epsilon$ and $t_j$ is enabled, then $t_j$ can fire at any moment.
• At any reachable marking $M_k$, an external observer reads the output vector $y_k = \varphi \cdot M_k$.

Definition 2.5. An IPN $Q$ is event-detectable if the firing of any transition $t_i \in T$ can be detected and distinguished from the knowledge of the indicated input symbols and a change in the output vector, i.e., $\forall t_i \in T$

• $\varphi C(\bullet, i) \neq 0$
• $\forall t_j \in T \{t_i\}, \lambda(t_i) \neq \lambda(t_j)$ or $\varphi C(\bullet, i) \neq \varphi C(\bullet, j)$.

3. REGULATION FRAMEWORK

Following the Control Theory terminology, the IPN system to be controlled is named Plant, and the desired behavior of the plant is described by an IPN system named Specification.

Definition 3.1. The plant is a safe event-detectable IPN $\langle Q_p, M_0 \rangle = \langle G, M_0, \Sigma_I, \lambda, \varphi \rangle$ that models the discrete event system to be controlled.
Definition 3.2. A specification model \( \langle Q_s, \tilde{M}_0 \rangle = \langle \tilde{G}, \tilde{M}_0, \Sigma_I, \tilde{\lambda}, \tilde{\phi} \rangle \) is a safe state machine IPN, where \( \tilde{\lambda} \) is a bijection (each transition is associated to a different symbol), and the system and the specification models have the same output vector dimension.

The regulation problem has been addressed in Santoyo et al. (2001); Sánchez-Blanco et al. (2004); Guevara-Lozano et al. (2019) for the case in which the plant marking is known. The problem can be formulated as the synthesis of a controller function \( \tilde{H} \) that provides the input symbols that have to be indicated to the plant in order to produce an output equal to that of the specification.

Definition 3.3. Let \( \langle Q_p, M_0 \rangle \) and \( \langle Q_s, M_0 \rangle \) be the IPN models of the plant and the specification, respectively. The regulation problem under complete information (i.e., assuming the plant marking is always known) consists in the computation of a controller function

\[
\tilde{H} : R(Q_p, M_0) \times R(Q_s, M_0) \times \tilde{T} \rightarrow \Sigma_I,
\]

such that \( \forall M_i \in R(Q_p, M_0), \forall M_j \in R(Q_s, M_0) \), the indication of the input symbols \( \tilde{H}(M_i, M_j, t_k) \), where \( t_k \) is the specification transition previously fired, will eventually lead the plant to a marking \( M_j \) such that \( \tilde{\phi}M_j = \tilde{\phi}M_1 \).

In this work, the regulation problem under partial information is considered. In this case, instead of the plant marking, the controller will use the plant output to compute and provide appropriate control actions. For this, the control problem is split in two stages. In the first one, the plant is driven from its initial marking, which is assumed to belong to the set of markings that agree with the initial observation \( \mu_0 = \{ M_i \in \{0,1\}^{|\tilde{P}|} | \tilde{\phi}M_i = y_0, B_0^c(M_0, 1) \} \), to a particular marking \( M_1 \) such that \( \tilde{\phi}M_1 = \tilde{\phi}M_1 \), where \( M_1 \) is the specification marking that can be reached after the first firing in the specification. During this stage, it is required to update each possible marking from \( \mu_0 \) according to the detected firings in the plant, otherwise stated, when a firing sequence \( \sigma_0 \) is detected a set \( \mu_k \) of possible current markings is computed as \( \mu_k = \{ M_k^c | M_0^c \tilde{\sigma}_k = M_k^c, M_0^c \in \mu_0 \} \).

Definition 3.4. Let \( \langle Q_s, M_0 \rangle \) be the IPN specification and let \( Q_p \) be the IPN plant structure. Assume \( M_0 \in \mu_0 \). The first stage of the regulation problem under partial information consists in the computation of a collection of controller functions \( F_k : \mu_k \rightarrow \Sigma_I \) for \( k \in \{0,1,2,\ldots\} \), where \( F_k \) represents the control actions that can be indicated after the \( k \)-th firing in the plant in order to drive the plant to a particular known marking \( M_1 \), where \( \tilde{\phi}M_1 = \tilde{\phi}M_1 \).

Under the assumption that the plant is safe, event-detectable and deterministic, it holds that \( |\mu_0| \geq |\mu_1| \geq \ldots \geq |\mu_k| \); thus, if the controller is non-blocking, there will be some step \( r \) such that \( |\mu_r| = 1 \), since the controller will lead all the possible markings to \( M_1 \). Safeness and event-detectability also implies that once the marking is known, it can be uniquely determined in the future evolution based on the input-output information, thus, the second stage becomes equivalent to the regulation problem under complete information.

4. CONTROLLER DESIGN WITH COMPLETE INFORMATION

The design of a regulation controller under complete information was already advanced in Santoyo et al. (2001); Sánchez-Blanco et al. (2004); Guevara-Lozano et al. (2019). Let us recall some basic ideas. For the controller synthesis, three main steps are required: 1) each specification reachable marking \( M \in R(Q_s, M_0) \) is associated to a plant reachable marking \( M \in R(Q_p, M_0) \) such that \( \tilde{\phi}M = \tilde{\phi}M \), this association can be described by a linear function \( \tilde{H} : R(Q_s, M_0) \rightarrow R(Q_p, M_0) \), defined such that \( \tilde{H}M = M \) (the computation of such function can be performed by an LPP (Santoyo et al. (2001); Sánchez-Blanco et al. (2004))); 2) each specification transition \( t \in \tilde{T} \) is associated to a controllable plant firing sequence \( \sigma \) such that \( M_i \xrightarrow{t} M_j \), where \( M_i \xrightarrow{\sigma} M_j \), \( \tilde{H}M_i = \tilde{H}M_j \) (the sequences can be computed by exploring the plant reachability graph, for instance by using the \( A^* \) algorithm (Santoyo et al. (2001); Sánchez-Blanco et al. (2004))); 3) based on the knowledge of the mapping \( \tilde{H} \) and the controllable sequences \( \sigma \), a controller can be synthesized as an agent that indicates suitable plant input symbols so the sequences \( \sigma \) are enforced when required by the specification. The first two steps are described in Santoyo et al. (2001); Sánchez-Blanco et al. (2004). The third step is implemented in the following algorithm in order to synthesize a controller function as defined above.

Algorithm 4.1. Calculation of \( \tilde{H} \).

1. **Input** Reachability sets of the plant \( H(Q_p, M_0) \) and the specification \( R(Q_s, M_0) \), specification’s transitions set \( \tilde{T} \), function \( \tilde{H} \), controllable firing sequences \( \sigma_a \) computed for each \( t_a \in T \).

2. **Output** Controller \( \tilde{H} \), complement \( \tilde{H} \).

3. for all \( M_i \in R(Q_s, M_0) \) do

4. for all \( t_a \in T \) do

5. if \( \exists M_j \in R(Q_s, M_0) \) such that \( M_i \xrightarrow{t_a} M_j \) then

6. Denote as \( \sigma_a = t_{a1} \ldots t_{am} \) the firing sequence such that \( \tilde{H}M_i \xrightarrow{t_{a1}} \tilde{H}M_{a2} \xrightarrow{t_{a2}} \ldots \xrightarrow{t_{am}} \tilde{H}M_j \).

7. Define the controller \( \tilde{H} \):

\[
\tilde{H}(\tilde{H}M_i, M_j, t_a) = \lambda(t_{a1})
\]

\[
\tilde{H}(M_{a2}, M_j, t_a) = \lambda(t_{a2})
\]

\[
\ldots
\]

\[
\tilde{H}(M_{am}, M_j, t_a) = \lambda(t_{am})
\]

8. Define the complement function \( \tilde{H} \):

\[
\tilde{H}(\tilde{H}M_i, M_j, t_a) =
\]

\[
\{ \lambda(t) | t \in T_c \{ t_{a1} \}, \tilde{H}M_i \xrightarrow{t}
\}
\]

\[
\tilde{H}(M_{a2}, M_j, t_a) =
\]

\[
\{ \lambda(t) | t \in T_c \{ t_{a2} \}, M_{a1} \xrightarrow{t}
\}
\]

\[
\ldots
\]

\[
\tilde{H}(M_{am}, M_j, t_a) =
\]

\[
\{ \lambda(t) | t \in T_c \{ t_{am} \}, M_{am} \xrightarrow{t}
\}
\]

9. end if

10. end for
11: end for
12: For the rest of elements in the domain $(M, \tilde{M}, \tilde{t}) \in R(Q_p, M_0) \times R(Q_s, \tilde{M}_0) \times \tilde{T}$, set $H(M, \tilde{M}, \tilde{t}) = \epsilon$, \($H(M, \tilde{M}, \tilde{t}) = \emptyset$\.

In this way, after the firing of a transition $\tilde{t}_a$ in the specification, leading to a marking $M_1$, the controller $H$ indicates input symbols in order to enforce the plant sequence $\sigma_a$, leading to $H(M_1)$. The controllability of $\sigma_a$ (explained in Santoyo et al. (2001); Sánchez-Blanco et al. (2004)) ensures that it is the only sequence that can occur when the controller $H$ indicates the corresponding symbols. Notice that if an uncontrollable transition $t_k$ belongs to the sequence, the function $H$ will correctly indicate the symbol $\lambda(t_k) = \epsilon$, meaning that the controller does not indicate a control action and it must wait for the firing of $t_k$.

The complement function $H$ provides the symbols of uncontrollable transitions that are enabled but not indicated. In the sequel, we will refer to those symbols as disabled by the controller $H$.

5. REGULATION UNDER PARTIAL INFORMATION

The regulation controller already introduced requires the knowledge of the plant’s marking to provide suitable control actions. When such information is not available, a question that arises is whether the controller can properly drive the plant from the initial marking leading the marking from $\tilde{M}_0 \tilde{t}_a \rightarrow \tilde{M}_1$. Moreover, consider a marking of the plant $M_1$ such that $\forall M \in \Pi$ completely known. Nevertheless, from simple examples we instead of the true marking of the plant that is not known. The following algorithm computes the controllers for each of the initial marking leading the marking from $\tilde{M}_0 \tilde{t}_a \rightarrow \tilde{M}_1$ and the $P$-flows loads.

Algorithm 5.1. Calculation of possible initial markings.

5.1 Calculation of Possible Initial Markings

The Algorithm 5.1 is proposed to compute the possible initial markings in the plant that do not enable uncontrollable transitions and agree with both the observed output and the $P$-flows loads.

Algorithm 5.1. Calculation of possible initial markings.

Next, after reaching $M_1$, the marking will be known. Moreover, safeness and even-detectability implies that once the marking is known, it can be uniquely determined in the future evolution based on the input-output information. Thus, the regulation problem under partial information is only required to be solved for the first firing of a specification transition.

5.2 Calculation of partial controllers

The following algorithm computes the controllers for each possible initial marking. For this, let us denote as $\tilde{t}_a$ the only enabled specification transition, i.e., $\tilde{M}_0 \tilde{t}_a \rightarrow \tilde{M}_1$. Moreover, consider a marking of the plant $M_1$ such that...
Algorithm 5.2. Calculation of controllers for $\mu_0$.

1: **Input** IPN plant structure $(Q_p, M_0)$ and $\mu_0$. Target marking $M_1$.
2: **Output** Controller $H_i$ for each $M_i \in \mu_0$.
3: **for** each $M_i \in \mu_0$ **do**
4: Define the function $\Pi^i$ as $\Pi^i M_0 = M_i$ and $\Pi^i M_1 = M_1$.
5: Compute a controllable sequence $\sigma^i_0$ such that $M_0 \xrightarrow{\sigma^i_0} M_1$, considering the constraint $\sigma^i_0 \geq 1$, where 1 is a column vector of dimension $|T|$ whose entries are 1's.
6: Compute the controller $H_i$ and its complement $H_i^c$ by using the Algorithm 4.1, but only for the possible specification marking $M_1$ in line 3 and the transition $\tilde{t}_a$ in line 4.
7: **end for**

The computed sequences intentionally involve all the transitions, thus only one sequence can be fired to reach $M_1$. The relation of the resulting functions $\Pi^i$ and sequences $\sigma^i_0$ is illustrated in fig. 1.

![Fig. 1. Functions $\Pi^i$ for the first stage control problem.](image)

5.3 Common events matrix and control function $F$

Under partial information, the controller may not know the current marking, instead of that, a set of different possible current markings is calculated. Under this scenario, a symbol must not be indicated if it is disabled by a controller complement of a possible current marking. To facilitate this task, a matrix describing the indicated and disabled symbols for each possible current marking is computed, after each transition firing.

Let us firstly introduce some notation. Given a set of possible initial markings $\mu_0$, when a firing sequence $\sigma_k$ of length $k$ is detected a set $\mu_k$ of updated markings is computed as $\mu_k = \{M_k | M_0 \xrightarrow{\sigma_k} M_k, M_0 \in \mu_0\}$.

The detected firings will allow to discard possible initial markings. A set of indexes $E_k$ will be used to record the current markings that are consistent with the observed input-output symbols, i.e., $i \in E_k$ if $M_i \in \mu_k$ is a possible current marking based on the observed input-output relation. In this way, the set of possible current markings is $\mu_k[E_k] = \{M_i \in \mu_k | i \in E_k\}$.

Definition 5.1. Let $(Q_p, M_0)$ and $(Q_s, M_0)$ be the IPN models of the plant and the specification, respectively. Let $\Pi^i$ and $H_i$ be the mapping function and the controller computed for an initial condition $M_i \in \mu_0$, respectively. Let $\mu_k$ be the set of possible current markings at the plant. Let $M_1$ be the specification marking reached after the firing of $\tilde{t}_a$, the only enabled transition from $M_0$. The matrix of common events is a square matrix of dimension $|\mu_k| \times |\mu_k|$, whose entries are defined as

$$\Omega_{\mu_k}(i, j) = |\{H_i^c(M_k, M_1, \tilde{t}_a) \cap H_j(M_k, M_1, \tilde{t}_a)\}|$$

If $\Omega_{\mu_k}(i, j) > 0$ it means that the symbol to be enforced by the $i$-th controller must be avoided by the $j$-th controller complement. Thus, if it is not known whether the system is at $M_k^1$ or at $M_k^0$, the controller scheme should not indicate the symbol given by the $i$-th controller $H_i(M_k^0, M_1)$, otherwise there would exist the possibility to fire an incorrect sequence. A transition $H_i(M_k^1, M_1, \tilde{t}_a)$ can safely fire only if all the entries of $\Omega_{\mu_k}(i, E_k)$ are null.

Therefore, the first stage controller function $F$ (Definition 3.4) is computed as

$$F(\mu_k, E_k) = \{H_i(M_k^0, M_1, \tilde{t}_a)| i \in E_k, \Omega_{\mu_k}(i, E_k) = 0\}$$

5.4 Regulation algorithm

The first stage of the regulation algorithm is implemented by the forthcoming Algorithm 5.3, assuming $M_0 \in \mu_0$, which drives the plant to a marking $M_1$. Since the plant is safe and event-detectable then the plant’s marking can be uniquely determined after any further firing. Thus, the second stage, which controls the plant for the subsequent specification firings, consists in a controller synthesized assuming complete information, as described in Section 4 but considering the initial markings of the plant and the specification as $M_1$ and $M_1$. Algorithm 5.3. Regulation based on partial information. Stage 1.

1: **Input** The plant and specification IPN models. The plant’s output signal $y$ and the detected firing sequence during the evolution.
2: **Output** Control action $u$ during the evolution. Updated markings $\mu_k$ and the set of possible marking indexes $E_k$ during the evolution.
3: **Synthesis:**
4: Let $\tilde{t}_a$ be the only enabled transition at the specification initial marking $M_0$ whose firing leads to $M_1$.
5: Compute the set of potential plant’s initial markings $\mu_0$, by using the Algorithm 5.1.
6: Compute a plant’s marking $M_1$ that is reachable from any marking of $\mu_0$ and that $\phi M_1 = \phi M_1$.
7: Compute the controllers $H_i(M_1, M_1, \tilde{t}_a)$ for the possible initial markings $\mu_0$, by using the Algorithm 5.2.
Operation: Initialize the plant marking and output index: $k = 0$. Thus, the set of possible initial states at the plant is $\mu_k = \mu_0$ and the current plant’s output is $y_k$. Initialize the set of possible marking indexes as $E_k = \{1, 2, \ldots, |\mu_0|\}$.

10: Wait until the firing of $t_a$.
11: Update the specification marking as: $M_1 = M_0 + C(\bullet, a)$. 
12: while the observed output $y_k \neq \varphi M_1$ do 
13: Compute $\Omega_{\mu_k}$ and $F(\mu_k, E_k)$ 
14: if $F(\mu_k, E_k) = \emptyset$ then 
15: STOP the algorithm 
16: else 
17: Select a symbol from $F(\mu_k, E_k)$, let $i$ be the associated index to such symbol. 
18: Indicate the selected symbol $u = H^i(M^i_k, \tilde{M}_1, \tilde{t}_a)$ 
19: if a firing is not detected in the plant then 
20: Eliminate $i$ from $E_k$, i.e., $E_k = E_k \setminus \{i\}$

34: end if 
35: end if 
36: end while

Remark 1. The control scheme guarantees that $\mu_k[E_k]$ includes the true marking and the fired sequence $\sigma_k$ is a prefix of the corresponding sequence $\sigma^\mu_k$, which leads the plant from the true initial marking $M^0_k$ to $M_k$. However, in some scenarios, the Algorithm 5.3 may block the plant (when $F(\mu_k, E_k) = \emptyset$), without reaching $M_1$.

5.5 Example

Consider the IPN model presented in the fig. 2, with initial marking $M_0 = [1 \ 0 \ 0 \ 0 \ 0 \ 0 \ 1 \ 1 \ 1] \ T$ and the specification model of the fig. 3.

Let us apply the synthesis procedure of the Algorithm 5.3. First, at the initial marking the output vector $y = [1 \ 0 \ 0 \ 1] \ T$ is detected (symbols $A$ and $D$). Thus, the Algorithm 5.1 computes the possible initial markings $M^1_0 = [1 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 1 \ 1 \ 1] \ T$, $M^0_0 = [0 \ 0 \ 0 \ 1 \ 1 \ 0 \ 0 \ 0 \ 1 \ 0 \ 0 \ 0] \ T$

Next, considering that $z_1$ is the only enabled transition at the specification, leading the system from $M_0$ to $M_1 = [0 \ 1 \ 0 \ 0 \ 1 \ 0 \ 0 \ 1 \ 1 \ 0 \ 0 \ 0] \ T$, a marking $M_1$ is computed such that $\varphi M_1 = \varphi M_1$. In particular, consider $M_1 = [0 \ 0 \ 1 \ 0 \ 0 \ 0 \ 1 \ 1 \ 1 \ 0 \ 0 \ 0] \ T$

The next step is to apply the Algorithm 4.1 to compute the controllers $H^1$ and $H^2$ that impose $\sigma^1_z$ and $\sigma^2_z$, respectively. In this way, the synthesis procedure is completed (the functions $H^1$ and $H^2$ are not written here due to lack of space).

Now, let us consider the operation procedure of the Algorithm 5.3. At the beginning, $\mu_0 = \{M^1_0, M^0_0\}$, $M = M_0$ and $E_0 = \{1, 2\}$. After the firing of $z_1$ at the specification, the marking specification becomes $M_1$, leading to the specification’s output $BD$. 

Fig. 2. PN plant, representing two identical processes described by places $p_1, p_2, p_3, p_4$ and $p_5, p_6, p_7, p_8$, respectively, and one shared resource, described by $p_2, p_6, p_9$. The second process can be down for repairing at the idle position $p_5$. For the production perspective, there is no distinction between the two processes, thus both have the same output symbols. Grey and white places represent nonmeasurable and measurable places, respectively.

Fig. 3. PN specification. In a first state, a process is required to be idle ($A$) while the resource is idle ($D$) as well. In a second state, a process is required to finish ($B$) while the resource is idle.

Next, a controller is designed for each possible initial marking in order to drive the system to $M_1$. In particular, the following controllable sequences are obtained (all the transitions were intentionally involved):

$\sigma^1_z = t_2t_3t_4t_1t_2t_3t_5t_6t_4t_6t_7t_8$

$\sigma^2_z = t_6t_7t_1t_2t_3t_4t_1t_2t_3t_5t_6t_7t_8$
At $\mu_0$, $H^1$ indicates $\lambda(t_2) = a$ and disables $\lambda(t_5) = f$, since $t_5$ is also enabled at $M_1$. On the other hand, $H^2$ indicates $\lambda(t_4) = d$ and disables $\lambda(t_1) = c$ and $\lambda(t_2) = a$, since both $t_1$ and $t_4$ are enabled at $M_2$. Thus, the common events matrix is

$$\Omega_{\mu_0} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} \quad (1)$$

The element 1 in the matrix means that the event indicated by the controller $H^1$ is disabled by controller $H^2$ (the event a, related to $t_2$ and $t_5$). On the contrary, the event indicated by the controller $H^2$ is not disabled by the controller $H^1$, since the second row of the matrix is null. Therefore, $F(\mu_0, E_0) = \{2\}$. Consequently, the index 2 is selected and the symbol $H^2(M_2, M_1, z_1) = \lambda(t_4) = d$ is indicated, i.e., the control action of the second controller is indicated. Nevertheless, since the true marking of the plant is $M_0$, at which no transition with symbol $d$ is enabled, then no transition fires. Thus, in accordance to the line 19 of the Algorithm 5.3, the index 2 is eliminated from $E_0$. Thus, $E_0 = \{1\}$ and $\mu_0[E_0] = [M_1]$, which is actually the true plant’s marking. Consequently, the common events matrix restricted to $E_k$ will be $[0]$ for further steps and thus the only active controller will be $H^1$, that will indicate the symbols to drive the plant from $M_0$ to $M_1$.

Now, let us consider again the operation procedure of the Algorithm 5.3, but in this case assuming that the true plant’s initial marking is $M_0 = M_2$. As in the previous case, the common events matrix is (1) as well. Thus, $2 \in E_0$ is selected and the symbol $H^2(M_2, M_1, z_1) = \lambda(t_4) = d$ is indicated. In this case, the transition $t_4$ fires at the plant, leading to the marking $M' = [0 0 0 1 0 0 0 0 0 0]$. Since $t_4$ was not enabled from $M_1$, then index 1 is removed from $E_1$. Thus, $E_1 = \{2\}$ and $\mu_1[E_1] = \{M_1\}$, where $M_1 = M'$, i.e., the algorithm has found the true plant’s marking. Consequently, the common events matrix restricted to $E_k$ will be $[0]$ for further steps and thus the only active controller will be $H^2$, which will indicate the symbols to drive the plant to $M_1$.

6. CONCLUSIONS AND FUTURE WORK

In this work, the regulation control problem for $PNs$ under partial information has been addressed. For this, the control problem is split in two stages: in the first stage, the plant is driven to a known marking $M_1$, the second stage is reduced to the full-information regulation case. The first stage control involves three steps: first, the set of possible initial markings is computed, second, a controller is synthesized for each possible initial marking, third, an algorithm is provided to select one control action from one controller and to discard possible initial markings based on the input/output observations. This scheme prevents the plant from firing unplanned sequences, however, the controller may block the plant.

It is left as future work to provide recovery mechanisms when the controller blocks the plant. Moreover, the case in which the plant initial output does not agree with the specification output will be considered.
