Primordial Gravitational Waves and Inflation: CMB and Direct Detection With Space-Based Laser Interferometers

Asantha Cooray

Abstract. The curl-modes of Cosmic Microwave Background (CMB) polarization probe horizon-scale primordial gravitational waves related to inflation. A significant source of confusion is expected from a lensing conversion of polarization related to density perturbations to the curl mode, during the propagation of photons through the large scale structure. Either high resolution CMB anisotropy observations or 21 cm fluctuations at redshifts 30 and higher can be used to delens polarization data and to separate gravitational-wave polarization signature from that of cosmic-shear related signal. Separations based on proposed lensing reconstruction techniques for reasonable future experiments allow the possibility to probe inflationary energy scales down to $10^{15}$ GeV. Beyond CMB polarization, at frequencies between 0.01 Hz to 1 Hz, space-based laser interferometers can also be used to probe the inflationary gravitational wave background. The confusion here is related to the removal of merging neutron star binaries at cosmological distances. Given the low merger rate and the rapid evolution of the gravitational wave frequency across this band, reliable removal techniques can be constructed. We discuss issues related to joint constraints that can be placed on the inflationary models based on CMB polarization information and space-based interferometers such as the Big Bang Observer.

1. CMB: At Present

The cosmic microwave background (CMB) is now a well known probe of the early universe. The temperature fluctuations in the CMB, especially the so-called acoustic peaks in the angular power spectrum of CMB anisotropies, capture the physics of primordial photon-baryon fluid undergoing oscillations in the potential wells of dark matter (Hu et al. 1997). The associated physics — involving the evolution of a single photon-baryon fluid under Compton scattering and gravity — are both simple and linear, and many aspects of it have been discussed in the literature since the early 1970s (Peebles & Yu 1970; Sunyaev & Zel’dovich 1970). The gravitational redshift contribution at large angular scales (e.g., Sachs & Wolfe 1968) and the photon-diffusion damping at small angular scales (e.g., Silk 1968) complete this description.

By now, the structure of the first few acoustic peaks is well studied with NASA’s Wilkinson Microwave Anisotropy Probe (WMAP) mission (e.g., Spergel
et al. 2003), while in the long term, ESA’s Planck surveyor\(^1\), will extend this
to a multipole of \(\sim 2000\). Given the improved resolution and better frequency
coverage, a variety of studies related to secondary anisotropies, e.g., Sunyaev-
Zel’dovich effect (Sunyaev & Zel’dovich 1980; Cooray, Hu & Tegmark 2000)
is expected. Beyond temperature fluctuations, detections of the polarization
anisotropy, related to density or scalar perturbations, have now been made by
DASI (Kovac et al. 2003; Leitch et al. 2004) and CBI (Readhead et al. 2004;
Cartwright et al. 2005), while the temperature-polarization power spectrum is
measured by WMAP (Kogut et al. 2003).

An interesting result from WMAP data is related to the very large (\(>10^\circ\))
angular scale polarization signal, which probes the local universe and associated
astrophysics instead of physics at the last scattering surface probed with polar-
ization at tens of arcminute scales. This local universe contribution arises when
the universe reionizes again and the temperature quadrupole begins to rescat-
ter to produce a new contribution to the polarization anisotropy at angular scales
concerning to the horizon at the new scattering surface (Zaldarriaga 1997).
The large-scale excess signal measured in the WMAP temperature-polarization
cross-correlation power spectrum is interpreted as rescattering with an optical
depth to electron scattering of \(0.17 \pm 0.04\) (Kogut et al. 2003).

Such an optical depth suggests early reionization; for example, if the uni-
verse reionized completely and instantaneously at some redshift, the measured
optical depth suggests a reionization redshift of \(\sim 17\) (\(\pm 5\)). Such a high optical
depth, in the presence of a \(>1\%\) neutral Hydrogen fraction from \(z \sim 6\) Sloan
quasars (Fan et al. 2002), suggests a complex reionization history. A complex,
and patchy, reionization, however, is expected if the reionization is dominated
by the UV light from first luminous objects, though to explain the high level of
the WMAP’s optical depth requires high star formation efficiency at redshifts of
order 15 with a possibility for a population of metal-free massive Pop III stars
(e.g., Cen 2003).

In general, one can only extract limited information related to the reion-
ization history from polarization peak at tens of degrees or more angular scales
(e.g., Hu & Holder 2003). One reason for this is the large cosmic variance associ-
ated with measurements at multipoles of \(\sim 10\). To extract detailed information
of the reionization process, one can move to temperature fluctuations generated
during the reionization era at angular scales corresponding to few arcminutes
and below. At these small angular scales, potentially interesting contributions
from high redshifts include a scattering contribution related to moving electrons
in ionized patches and fluctuations in the moving electron population (e.g., San-
tos et al. 2003), and a thermal Sunyaev-Zel’dovich effect related to the first
supernovae bubbles (Oh et al. 2003). The same redshift ranges are expected to
be illuminated in the near-infrared band between 1 to 3 \(\mu\)m in the form of spatial
fluctuations to the cosmic IR background (e.g., Santos et al. 2002; Salvaterra
et al. 2003; Cooray et al. 2004). Potentially interesting studies to extract more
information related to the reionization process include brightness temperature
fluctuations of the redshifted 21 cm line emission by neutral HI prior to and
during Hydrogen (e.g., Zaldarriaga et al. 2004), and cross-correlation studies

\(^{1}\)http://astro.estec.esa.nl/Planck/
between small angular scale effects in CMB and maps at other wavelengths (Cooray 2004a; Cooray 2004b; Salvaterra et al. 2005). Upcoming experiments such as the South Pole Telescope and the Atacama Cosmology Telescope, combined with near-IR and 21 cm maps, will provide some of the first possibilities in this direction.

2. Inflation: CMB and Space-Based Laser Interferometers

We first summarize basic aspects related to inflation under the assumption of a single scalar field model. Our derivations, however, are applicable to multi-field theories with few alterations (Lidsey et al. 1997). In general, constraints on inflation are obtained by comparing theoretically calculated scalar and tensor metric — gravitational waves — perturbations to direct (in the case of space-based detectors) and indirect (such as CMB) measurements of these perturbations.

The tensor and scalar perturbations are determined by the evolution of the scalar field, $\phi$, (the ‘inflaton’ field) and the scale factor, $a$, with time. The equation of motion for a scalar field with a self-interaction potential, $V(\phi)$, is given by,

$$\ddot{\phi} + 3H\dot{\phi} + V' = 0,$$

Figure 1. Power spectrum for the temperature anisotropies in the fiducial $\Lambda$CDM model with $\tau = 0.1$. In the case of temperature, the curves show the local universe contributions to CMB due to gravity (ISW and lensing) and scattering (Doppler, SZ effects, patchy reionization). We refer the reader to Cooray, Baumann & Sigurdson (2004) for a recent review on large scale structure contributions to temperature anisotropies.
where $H$ is the Hubble parameter and the prime refers to differentiation with respect to the field, $\phi$. The evolution of the Hubble parameter is determined by the energy density, $\rho$, which we suppose is dominated by the energy density
Gravitational Waves and Inflation

associated with the inflaton field,

\[ H^2 = \frac{8\pi}{3M_{pl}^2} \rho = \frac{8\pi}{3M_{pl}^2} \left( \frac{1}{2} \dot{\phi}^2 + V(\phi) \right), \]  

(2)

where \( M_{pl} \equiv G^{-1/2} = 1.2 \times 10^{19} \text{ GeV} \). The initial curvature redshifts away by the time the scales corresponding to the current Hubble horizon left the inflationary horizon. In general, an exact analytic solution for the spectrum of scalar and tensor perturbations does not exist. In order to facilitate analytic solutions, one generally resorts to the 'slow-roll' expansion, where the equations of motion are expanded in terms of the inflaton potential and its derivatives (Liddle, Parsons & Barrow 1994). Motivation for this expansion can be understood by noting that the equation of motion for the inflaton field is formally equivalent to the equation of motion of a mass moving under a potential \( V \) with damping due to the cosmological expansion. The slow roll expansion supposes that the motion of the field reaches a 'terminal velocity' in which the potential energy dominates over the kinetic energy and the acceleration of the field is negligible. In order to quantify these assumptions, the slow-roll parameters are used

\[ \epsilon \equiv \frac{M_{pl}^2}{16\pi} \left( \frac{V'}{V} \right)^2, \quad \text{and} \quad \eta \equiv \frac{M_{pl}^2}{8\pi} \frac{V''}{V}. \]  

(3)

Under the assumption that \( \epsilon, |\eta| \ll 1 \), the approximate 'slow-roll' evolution equations are

\[ H^2 \approx \frac{8\pi}{3M_{pl}^2} V, \quad \text{with} \quad 3H\dot{\phi} + V' \approx 0. \]  

(4)

On a given length scale, scalar perturbations start as quantum fluctuations in otherwise classical fields well within the horizon. Here, flat space-time quantum field theory is appropriate. As the scale factor quasi-exponentially increases, the length scale is stretched beyond the inflationary horizon. The quantum fluctuations are then amplified and become classical perturbations to the metric (Guth & Pi 1982). In order to study scalar and tensor perturbations, we consider their power spectra. It can be shown that within the slow roll approximation the amplitude of power spectra can be written as (Stewart & Lyth 1993, Lidsey et al. 1997),

\[ P_S(k) = \frac{1}{\pi} \frac{H^2}{M_{pl}^2} \epsilon \approx \frac{128\pi}{3M_{pl}^6} \frac{V^3}{V'}/V', \]  

(5)

\[ P_T(k) = \frac{16}{\pi M_{pl}^2} H^2 \approx \frac{128}{3} \frac{V}{M_{pl}^4}. \]  

(6)

where \( S \) and \( T \) refer to scalar and tensor perturbations respectively. The right hand sides of the above equations are to be evaluated when a given comoving length scale crosses the inflationary horizon with \( k_0 = aH \). In order to quantify how these power spectra change with scale, one considers their power-law
spectral indices (Liddle and Lyth 1992),
\[
 n_S(k) \equiv 1 - \frac{d \ln P_S}{d \ln k} \approx 1 - 6 \epsilon + 2 \eta, \tag{7}
\]
\[
 n_T(k) \equiv \frac{d \ln P_T}{d \ln k} \approx -2 \epsilon. \tag{8}
\]

If the potential is flat enough, higher order spectral parameters, which are higher order in the slow roll parameters, can be ignored (Stewart & Lyth 1993). As long as the slow roll parameters can be considered constant, we are able to write the power spectra as power-laws with spectral indices given by the above expressions. It can then be shown that,
\[
 \Delta \epsilon \approx \Delta \eta \approx O(\epsilon^2) \Delta \ln k. \tag{9}
\]

Currently, CMB data probe up to \(l_{\text{max}} \sim 1000\) corresponding to \(\Delta \ln k \sim 1\). Current observations constrain \(\epsilon \leq 0.1\) at scales corresponding to the current Hubble horizon. Therefore, although CMB observations do cover a few orders of magnitude in wavenumber, to within second order in the slow roll parameters, they can be considered constant over the range probed by the CMB. This implies that the perturbation power spectra will appear as approximate power laws, expanded around some 'pivot' wavenumber, \(k_0\) (Leach et al. 2002),
\[
 P_S(k) \approx P_S(k_0) \left( \frac{k}{k_0} \right)^{1 - n_S}, \quad \text{and} \quad P_T(k) \approx P_T(k_0) \left( \frac{k}{k_0} \right)^{n_T}. \tag{10}
\]

In the case of WMAP these parameters are evaluated at \(k_0 = 0.002\text{Mpc}^{-1}\) (Spergel et al. 2003; Peiris et al. 2003). Using the expressions for the amplitudes and spectral indices in terms of the slow roll parameters, we are able to solve for the potential and its first two derivatives and thereby use observations to constrain the form that this potential can take. We have,
\[
 V \approx \frac{3P_T}{128} M_{\text{pl}}^4, \tag{11}
\]
\[
 |V'| \approx \sqrt{8\pi n_T} \frac{3}{128} P_T M_{\text{pl}}^3, \tag{12}
\]
\[
 V'' \approx \frac{3\pi}{32} P_T (n_S - 1 - 3n_T) M_{\text{pl}}^2, \tag{13}
\]
\[
 \frac{P_T}{P_S} \approx -16n_T, \tag{14}
\]

and all of the spectral parameters are to be evaluated at the pivot wavenumber, \(k_0\). The last expression is known as the consistency relation and is true only in single-field inflationary model. The expression relaxes to an inequality in the case of multi-field models. It is a consequence of the fact that both scalar and tensor spectra are determined from the dynamics of a single scalar field, so they are not independent (Lidsey et al. 1997, Liddle & Lyth 2000).
2.1. CMB

Though acoustic oscillations in the temperature anisotropies of CMB suggest an inflationary origin for primordial perturbations, such as in the WMAP data (Peiris et al. 2003), it has been argued for a while that the smoking-gun signature for inflation would be the detection of a stochastic background of gravitational waves (e.g., Kamionkowski & Kosowsky 1999). Since CMB probes horizon to super-horizon scales, inflation is the only known mechanism to casually produce a stochastic background of gravitational waves at such large wavelengths (e.g., Starobinsky 1979). Note that the amplitude of the gravitational wave background is highly unknown. Since the amplitude of these inflationary gravitational waves is proportional to $V(\phi)$ during inflation, the amplitude of gravitational-wave induced B-mode polarization anisotropies directly constrains the energy scale of inflation $V^{1/4}$. Relative to COBE normalization, the relation between the energy scale and the ratio of tensor-to-scalar fluctuations is $V^{1/4} = 3.0 \times 10^{-3}(T/S)^{1/4}M_{pl}$ (Turner & White 1996). The current limit from CMB anisotropy data, based on large angular-scale CMB temperature fluctuations, suggests an upper limit of order $2 \times 10^{16}$ GeV (Melchiorri & Odman 2003).

Instead of temperature fluctuations (where dominant scalar perturbations confuse the detection of tensor contribution), the gravitational-waves can be studied through their distinct signature in the CMB polarization in the form of a contribution to the curl, or magnetic-like, component (Kamionkowski et al. 1997; Seljak & Zaldarriaga 1997). There is no contribution from the dominant scalar, or density-perturbation, contribution to these curl modes in linear theory. Secondary effects related to density perturbations, however, do produce signals in the curl-mode and confuse the detection of inflationary gravitational-wave signal.

Among these, the few percent conversion of E to B from cosmic shear modification to the polarization pattern by the intervening large scale structure is important (Zaldarriaga & Seljak 1998). These lensing-induced curl modes introduce a noise from which gravitational waves must be distinguished in the CMB polarization.

Gravitational lensing of the CMB photons by the mass fluctuations in the large-scale structure is now well understood (e.g., Hu 2000; Hu & Cooray 2001). The lensing effect can be described through a remapping process involving angular deflections resulting along the photon path:

$$\hat{\Theta}(\hat{n}) = \Theta(\hat{n} + \nabla \phi)$$

$$= \Theta(\hat{n}) + \nabla_i \phi(\hat{n}) \nabla^i \Theta(\hat{n}) + \frac{1}{2} \nabla_i \phi(\hat{n}) \nabla_j \phi(\hat{n}) \nabla^i \nabla^j \Theta(\hat{n}) + \ldots , (15)$$

where the deflection angle on the sky is given by the angular gradient of the lensing potential, $\alpha(\hat{n}) = \nabla \phi(\hat{n})$, which itself is a projection of the gravitational potential, $\Phi$ (see e.g. Kaiser 1992),

$$\phi(\hat{m}) = -2 \int_0^{r_0} dr \frac{dA(r)}{dA(r_0)} \Phi(r, \hat{m} r) . (16)$$

The quantities here are the conformal distance or lookback time, from the observer ($r$) and the analogous angular diameter distance $d_A$. The lensing potential
Cooray

in equation (16) can be related to the well known convergence generally encountered in conventional lensing studies involving galaxy shear (Kaiser 1992)

\[
\kappa(\hat{m}) = \frac{1}{2} \nabla^2 \phi(\hat{m}) \\
= - \int_0^{r_0} dr \frac{dA(r) dA(r_0 - r)}{dA(r_0)} \nabla_\perp^2 \Phi(r, \hat{m}r),
\]

(17)

where note that the 2D Laplacian operating on \( \Phi \) is a spatial and not an angular Laplacian. Expanding the lensing potential to Fourier moments,

\[
\phi(\hat{n}) = \int \frac{d^2 l}{(2\pi)^2} \phi(l) e^{i\hat{n} \cdot \hat{\ell}},
\]

(18)

we can write the usually familiar quantities of convergence and shear components of weak lensing as

\[
\kappa(\hat{n}) = - \frac{1}{2} \int \frac{d^2 l}{(2\pi)^2} l^2 \phi(l) e^{i\hat{n} \cdot \hat{\ell}} \\
\gamma_1(\hat{n}) \pm i \gamma_2(\hat{n}) = - \frac{1}{2} \int \frac{d^2 l}{(2\pi)^2} l^2 \phi(l) e^{\pm i2(\phi - \varphi)} e^{i\hat{n} \cdot \hat{\ell}}.
\]

(19)

Taking the Fourier transform, as appropriate for a flat-sky, we write

\[
\tilde{\Theta}(\ell_1) = \int d\hat{n} \tilde{\Theta}(\hat{n}) e^{-i\hat{n} \cdot \hat{\ell}_1} \\
= \Theta(\ell_1) - \int \frac{d^2 l_1}{(2\pi)^2} \Theta(\ell_1') L(\ell_1, \ell_1'),
\]

(20)

where

\[
L(\ell_1, \ell_1') = \phi(\ell_1 - \ell_1') (\ell_1 - \ell_1') \cdot \ell_1' + \frac{1}{2} \int \frac{d^2 l_1''}{(2\pi)^2} \phi(l_1'') \\
\times \phi^*(l_1'' + \ell_1' - \ell_1) (l_1'' \cdot \ell_1') (l_1'' + \ell_1' - \ell_1) \cdot \ell_1'.
\]

(21)

The lensed power spectrum, according to the present formulation, is discussed in Hu (2000) and we can write

\[
\tilde{C}_l^{\Theta} = \left[ 1 - \int \frac{d^2 l_1}{(2\pi)^2} C_{l_1}^{\phi\phi} (l_1 \cdot l_1)^2 \right] C_l^{\Theta} + \int \frac{d^2 l_1}{(2\pi)^2} C_{l_1}^{\Theta} C_{l_1'}^{\phi\phi} (1 - l_1) \cdot l_1]^2.
\]

(22)

Since the lensing effect involves the angular gradient of CMB photons and leaves the surface brightness unaffected, its signatures are at the second order in temperature. Effectively, lensing smooths the acoustic peak structure at large angular scales and moves photons to small scales. Note that the approach above treats the deflection angle as a perturbative parameter. Such an approximation
breaks down at angular scales corresponding to roughly the rms deflection angle of a CMB photon (∼ a few arcminutes). While the approach can be extended to higher order (e.g., Cooray 2004c), the numerical calculation becomes increasingly time consuming. The development of numerically fast, but still accurate, approaches (e.g., Challinor & Lewis 2005) will aid in analysis data from future high resolution CMB experiments. To put rough estimates on the expected changes due to lensing, the mean gradient is of order \( \sim 15 \mu K \) arcmin\(^{-1}\) and with deflection angles or order 0.5 arcmin or so from massive clusters, the lensing effect results in temperature fluctuations of order \( \sim 5 \) to 10 \( \mu K \). In Fig. 1, we show the effect of lensing on temperature fluctuations where power is transferred from acoustic peaks to the damping tail of anisotropy spectrum.

To calculate the lensing contribution to the polarization, we follow the notation in Hu (2000). Introducing,

\[
\pm \tilde{X}(\hat{n}) = \pm X(\hat{n} + \nabla \phi) \approx \pm X(\hat{n}) + \nabla_i \phi(\hat{n}) \nabla^i \pm X(\hat{n}) + \frac{1}{2} \nabla_i \phi(\hat{n}) \nabla_j \phi(\hat{n}) \nabla^i \nabla^j \pm X(\hat{n}),
\]

where \( \pm X = Q \pm iU \) represent combinations of the Stokes parameters. The lensing effect is again to move the photon propagation directions on the sky. In Fourier space, assuming flat-sky, we can consider the E- and B-mode decomposition introduced in Kamionkowski et al. (1997; Seljak & Zaldarriaga 1997) such that

\[
\pm \tilde{X}(l) = \pm X(l) - \int \frac{d^2 l_1}{(2\pi)^2} \pm X(l_1) e^{\pm 2i(\varphi_l - \varphi_{l_1})} L(l, l_1).
\]

(23)

Since primordial \( B(l) \), due to the gravitational wave contribution, is small, we can make the useful approximation that

\[
\tilde{E}(l) = E(l) - \int \frac{d^2 l_1}{(2\pi)^2} |E(l_1)| \cos(\varphi_{l_1} - \varphi_l) \phi(l - l_1) (l - l_1) \cdot l_1,
\]

\[
\tilde{B}(l) = - \int \frac{d^2 l_1}{(2\pi)^2} |E(l_1)| \sin(\varphi_{l_1} - \varphi_l) \phi(l - l_1) (l - l_1) \cdot l_1,
\]

(25)

Under this approximation, the lensed polarization power spectra can be expressed in terms of \( C_{l}^{\phi\phi} \) and, in the case of B-modes, we can write

\[
\tilde{C}_{l}^{BB} = C_{l}^{BB,IGW} + \frac{1}{2} \int \frac{d^2 l_1}{(2\pi)^2} C_{l-1_1}^{\phi\phi} |(l - l_1) \cdot l_1|^2 C_{l_1}^{EE} [1 - \cos(4\varphi_{l_1})],
\]

(26)

where \( C_{l}^{BB,IGW} \) is the contribution due to IGWs and the contribution in the second line is the confusion that must be removed. To achieve this separation, one must obtain information on the integrated potential out to last scattering surface. One can effectively extract information related to the lensing potential, and the integrated dark matter density field responsible for the lensing effect, via quadratic statistics applied to CMB temperature and polarization maps (Hu
Figure 3. CMB B-mode polarization. The curve labeled ‘IGWs’ is the IGW contribution with a tensor-to-scalar ratio of 0.1 with (solid line; $\tau = 0.17$) and without (dashed line) reionization. The curve labeled ‘lensing’ is the total lensing confusion to B-modes. Thin lines show the residual B-mode lensing contamination for removal of with lensing out to $z_s$ while thick lines show estimates of the residual confusion from CMB experiments alone using quadratic estimators with an ideal noise-free experiment (dashed line), and likelihood methods using a high resolution/sensitivity experiment (dot-dashed). The noise curve of latter this experiment, with 2 arcminute beams and a pixel noise of 0.25 $\mu$K-arcminute, is the curve labeled ‘High-Res’. Bias-limited lensing information to $z_s > 10$ improves upon the limit to the IGW amplitude based on quadratic statistics, and the likelihood level can be reached with $z_s \sim 30$. If $z_s \sim 100$ an additional order-of-magnitude in the IGW amplitude could be probed. The curve labeled ‘Low-Res’ is the noise curve for a lower resolution CMB polarization experiment with 30 arcminute beams sufficiently sensitive to detect IGWs when paired with a cosmic 21-cm lensing reconstruction. See, Sigurdson & Cooray (2005) for details.
Gravitational Waves and Inflation

For tensor-to-scalar ratios $T/S$ below $2.6 \times 10^{-4}$ or $V^{1/4}$ below $4.6 \times 10^{15}$ GeV the IGW signal is completely confused by the lensing contaminant (Lewis et al. 2002). To bypass this limit one must separate the lensing induced B-modes from those due to IGWs (Kesden et al. 2002; Knox & Song 2002; Seljak & Hirata 2004). Clearly, the lensing confusion could be exactly removed if one knew the three-dimensional distribution of mass out to the CMB last-scattering surface. However, knowledge of the projected quantity $\phi(\hat{n})$ is sufficient. One way to estimate $\phi(\hat{n})$ is by using quadratic estimators or maximum likelihood methods to statistically infer the deflection-angle field given temperature and polarization anisotropies (Hu 2001b; Hu & Okamoto 2002). These method allow one to detection down $10^{15}$ GeV (Kesden et al. 2002; Knox & Song 2002). In the case of likelihood methods, one does not have an obvious ultimate limit, however, the residual lensing noise is still above the detector noise even for highest sensitive polarization maps. While this is encouraging, it is useful to consider alternative techniques to reduce the confusion. A useful way to estimate $\phi(\hat{n})$, but out to a high-redshift, is by observing the weak-lensing distortions of the shapes of objects of a known average shape at redshift $z_s$. As the CMB source redshift is at 1100, observations of the weak lensing of galaxies, out to a redshift of $\sim 1$–2, can not be used to effectively delens CMB maps because a large fraction of the lensing contamination (55% at $l = 1000$) comes from structure at $z > 3$. A possibility exists in the form anisotropies in the 21 cm brightness temperature fluctuations during the era and prior to reionization (Sigurdson & Cooray 2005).

For example, using a quadratic reconstruction of the deflection field of 21 cm anisotropies out to a source redshift of 30, in conjunction with a low-resolution but high signal-to-noise CMB polarization experiment, could detect $T/S > 2.5 \times 10^{-5}$ or $V^{1/4} > 2.6 \times 10^{15}$ GeV if 21 cm fluctuations measurements are limited to $l \sim 5000$. If the resolution in 21 cm observations is improved so that one can measure 21 cm brightness temperature anisotropy spectrum out to $l \sim 10^5$, one can improve down to $T/S > 1.0 \times 10^{-6}$ or $V^{1/4} > 1.1 \times 10^{15}$ GeV. This limit is comparable to using CMB lensing information alone from high sensitive maps at 2 arcminute resolution (Seljak & Hirata 2004). To achieve such a resolution one requires roughly a space mission with an aperture of diameter $\sim 6(100 \text{GHz}/\nu)$ meters. In the case of CMB lens-cleaning with information from 21 cm observations, as the IGW signal is at multipoles of 100 (in the case of recombination bump) and/or 20 (in the case of reionization with optical depths around 0.1), the CMB data need not be high resolution. Since lensing information is not extracted from CMB observations, the optimal observing strategy is to integrate over a few square degree patch of the sky as proposed in Kamionkowski & Kosowsky (1998). Thus, it is conceivable that the Inflationary Probe of NASA’s Beyond Einstein Program can be designed in combination with a cosmic 21-cm radiation experiment. Such a cosmic 21-cm radiation experiment could be extremely exciting for reasons involving 21 cm fluctuations alone where one probes the small scale structure of the Universe at high redshifts. For a bias-limited reconstruction out to a $z_s \sim 100$, the limit on the tensor-to-scalar ratio is $7.0 \times 10^{-8}$ or $V^{1/4} > 6.0 \times 10^{14}$ GeV. For $z_s \sim 200$, the maximum redshift where 21-cm fluctuations are expected to be nonzero, one could probe down to $V^{1/4} > 3 \times 10^{14}$ GeV.
2.2. Space-based Laser Interferometers

Beyond CMB polarization data, there is long-term interest, as part of NASA’s Beyond Einstein Program, to launch a space-based laser interferometer (Big Bang Observer) to directly detect the presence of relic stochastic gravitational background today from inflation. The CMB detection and the detection of the laser interferometers provide unique opportunities to study properties related to inflationary physics. To understand requirements for the direction detection, we summarize some of the key aspects related to the stochastic background.

The evolution of tensor perturbations, for scales inside the horizon subsequent to inflation, is governed by the massless Klein-Gordon equation

$$\frac{d^2 h_k}{d\tau^2} + 2\frac{1}{a} \frac{da}{d\tau} \frac{dh_k}{d\tau} + k^2 h_k = 0$$

subject to the boundary conditions, $h_k(0) = P_T(k)^{1/2}$ and $h'_k(0) = 0$. $\tau$ is conformal time, which is related to cosmic time by the differential relation, $dt/d\tau = a$. We define $g_k(\tau) \equiv h_k(\tau)a(\tau)$. With this definition, we are able to rewrite the above equation,

$$\frac{d^2 g_k}{d\tau^2} + \left(k^2 - \frac{1}{a} \frac{d^2 a}{d\tau^2}\right) g_k = 0$$

There are two limiting behaviors for $g_k$: before horizon entry $g_k \propto a \rightarrow h_k =$ constant; after horizon entry $g_k$ will oscillate which implies $h_k$ will oscillate with an amplitude decreasing as $1/a$. Therefore, the current spectrum of gravitational waves is determined by the primordial power spectrum and by the rate at which scales enter the horizon (i.e. the evolution of the scale factor): $h = h_0a_k/a$. At horizon crossing, note that $k = a_k H_k$.

During radiation domination, $H \propto a^{-2}$, so that $k = 1/a_k$ and during matter domination $H \propto a^{-3/2}$, so that $k = 1/a_k^{1/2}$. From these relations, we find that,

$$h_k \propto k^{-1} \quad \text{(Radiation Domination)}$$
$$h_k \propto k^{-2} \quad \text{(Matter Domination)}$$

In order to quantify these scalings, a transfer function is used (Turner, White & Lidsey 1993). We note that during the matter dominated epoch, $a \propto \tau^2$ and the above equation becomes a Bessel equation (see, discussions in Pritchard & Kamionkowski 2004). Requiring that the solution approach unity at $\tau = 0$, we find that

$$h_k(\tau) = 3\frac{j_1(k\tau)}{k\tau}$$

Using this, we define the transfer function, $T(k/k_{eq})$ (where $k_{eq}$ is the wavenumber of matter-radiation equality $\approx 6.22h^2 \times 10^{-2}$ Mpc$^{-1}$) as,

$$T(k) \equiv \sqrt{\frac{\langle h_k(k\tau)^2 \rangle}{\langle (3j_1(k\tau)/(k\tau))^2 \rangle}}$$
where the average is taken over several periods around the time that we want to evaluate the transfer function. From our scaling arguments, the transfer function must take the form of

\[ T(k) = \sqrt{c_0 + c_1 k/k_{eq} + c_2 (k/k_{eq})^2} \]  

(33)

The spectrum as seen by a gravitational wave detector is (Turner, White & Lidsey 1993),

\[ \Omega_{GW}(k) = \frac{3}{128} P_T(k_0) \left( \frac{k}{k_0} \right)^{n_T} \frac{T(k/k_{eq})^2}{(k\tau_0)^2} \]  

(34)

where \( \tau_0 \approx 2H_0^{-1} \approx 10^4 \) Mpc for \( H_0 = 70 \) km/s Mpc. \( \Omega_{GW} \) is the ratio of the energy density in gravitational energy to that of the closure density, \( \rho_c \sim 10^{-29} \text{ gm/cm}^3 \). In order to determine the values for \( c_1, c_2 \), and \( c_3 \) we need to numerically integrate the evolution equation and determine \( T(k) \). Since space-based gravitational wave detectors that are under consideration for detection of inflationary gravitational waves have sensitivities around a frequency of \( \sim 0.01 \text{Hz} \), our analysis considers only wave numbers in excess of \( k_{eq} \). Therefore, the values determined by Turner, White and Lidsey (1993; \( c_0 = 1, c_1 = 1.34, c_2 = 2.5 \) ) are applicable, even though they assumed the universe was filled with only matter and radiation.

Here, we have ignored one important detail; the right hand side of time evolution equation is not strictly zero. Instead, tensor perturbations are sourced by anisotropic stress in the cosmic fluid. The largest source of such stresses comes from the free-streaming of relic neutrinos (Weinberg 2004). It can be shown that these neutrinos cause the amplitude of gravitational waves that enter the horizon well before matter radiation equality to be damped by a factor of \( \sim 0.8 \). This will influence the amplitude of gravitational waves detectable with space-based detectors. Similarly, the amplitude seen by CMB polarization is damped between a few to a few ten percent with longest waves damped less.

In Fig. 4, we show the amplitude of tensor fluctuations related to a background of inflationary gravitational waves as a function of the gravitational wave frequency. We plot roughly 25 orders of magnitude in the frequency from super-horizon to horizon scales probed by CMB to a million-km wavelength modes detectable with space-based interferometers. For reference, we also show various existing limits on the stochastic backgrounds based on calculations related to the Big Bang Nucleosynthesis (Allen 1996) to timing-limit for millisecond pulsars (e.g., Thorsett & Dewey 1996). An extended discussion related to such limits are in Seto & Cooray (2005). The left-panel of Fig. 3 shows \( \Omega_{GW} \) which is the fractional density contribution from a background of stochastic gravitational waves with the density \( \rho_{GW} \):

\[ \Omega_{GW}(f) = \frac{1}{\rho_c} \frac{d\rho_{GW}}{d\log f} . \]  

For reference, in the right-panel, we also plot the dimensional strain \( h_c(f) \) given by the \( h_c^2(f) = f S_h(f) \) where \( S_h(f) \) is the power spectral density of gravitational waves, \( \langle h(f)h(f') \rangle = S_h(f) \). The two quantities, \( \Omega_{GW} \) and \( S_h \) are related
through (Maggiore 2000),

$$\Omega_{GW}(f) = \frac{4\pi^2}{3H_0^2} f^3 S_h(f).$$  \(36\)

In addition to single detector noise levels, in Fig. 4, we also show the improvement when the signal from two independent detectors can be combined through a correlation analysis between the two detectors (e.g., Maggiore 2000). Such a correlation increases sensitivity to a stochastic background such that,

$$h_{\text{2detector}}^2 = 1.12 \times 10^{-2} \gamma(f) \frac{h_n(k)}{F} \left(\frac{1\text{Hz}}{\Delta f}\right)^{1/4} \left(\frac{1\text{yr}}{T}\right)^{1/4}$$  \(37\)

where \(\Delta f\) is the bandwidth over which the signals can be correlated, \(T\) is the integration time, and \(F\) is a filling factor, which accounts for the fact that a primordial stochastic background will be isotropic on the sky, but the detector will only be sensitive to a fraction of the sky. For omni-directional interferometers, such as the Laser Interferometer Space Antenna (LISA), \(F = 2/5\), while \(h_n(k)\) is the characteristic strain due to detector noise. The single-detector sensitivity is \(h_n(k)/F\). Here, \(\gamma(f)\) is the overlap-reduction factor that takes into account the relative orientation and configuration of two interferometer systems. This correction results in an overall reduction of noise from the naive estimates that do not take into account detail configuration and motion of the detectors with respect to each other in the orbit (e.g., Ungarelli & Vecchio 2001).

For a correlation analysis, the increase in sensitivity is under the assumption that the detector noises are independent between the two detectors, while the only correlation expected is due to stochastic signals such as inflation. We note here that for the single detector case, the minimum observable strain is independent of the integration time while for a correlation analysis, long-term observations are essential. While LISA will not allow an opportunity for such a correlation analysis, some concept studies for the Big Bang Observer consider two systems such that the improvement related to the correlation analysis can be exploited.

In Fig. 5, we concentrate on the frequency regime relevant for space-based detectors. In addition to detector noise and the expected level of amplitude related to inflationary gravitational waves, based on the energy scale of inflation, we also show the confusion related to foreground stochastic backgrounds related to merging compact binaries. These signals include cosmological neutron star-neutron star binaries (e.g., Schneider et al. 2001), white dwarf-white dwarf binaries (e.g., Farmer & Phinney 2003), neutron star-white dwarf binaries (e.g., Cooray 2004d), and the background related to single rotational neutron stars (Ferrari et al. 1999). In addition to these compact binaries, a cosmological background of hypothetical Pop III supernovae could potentially contribute a substantial background at frequencies corresponding to the Big Bang Observer (e.g., Buonanno et al. 2004).

To jointly constrain the inflaton potential using observations at horizon-scale wavelengths with CMB and million-km scale with space-based interferometers, one can extend the CMB-based technique discussed in Turner (1993). The detectable amplitude, and the spectral index, with space-based detectors
Figure 4. Here we show the predicted gravitational wave background due to inflation along with various current and planned detectors and known upper limits on a cosmological stochastic gravitational wave background. We follow Maggiore (2000) and take the correlated sensitivity to be approximately $10^{-4}$ better than the uncorrelated sensitivity. The sensitivity of LISA is obtained from Shane Larson’s website, http://www.srl.caltech.edu/~shane/sensitivity/. The sensitivity for BBO correlated is obtained from Buonanno et al. (2004). We estimate the sensitivity for BBO by increasing the BBO curve by 4 orders of magnitude. The sensitivity for the ultimate DECIGO is estimated in Seto et al. (2001). The BBN constraint comes from the requirement that the total energy density in gravitational waves be less than the energy density in other forms of radiation at BBN, so that the abundances of the light elements remain in agreement with observations (Allen 1996). Only length scales less than the horizon size at BBO contribute and are constrained by this argument. Millisecond pulsar timing observations have constrained the energy density in a stochastic background to be below $\sim 10^{-8}$ around $f \sim 10^{-8}$ Hz. Curves corresponding to an inflationary produced background are shown in magenta for three different inflationary energy scales, $E_{\text{inf}}$ (Turner, White & Lidsey 1993). As stated in the text, COBE/WMAP constrain the energy scale of inflation to be below approximately, $2 \times 10^{16}$ GeV. As is described in the text, due to confusion with weak lensing, a detection of tensor perturbations in the polarization of the CMB can occur only if the energy scale of inflation is greater than $\sim 2 \times 10^{15}$ GeV. As of now, there is no planned gravitational wave observatory capable of detecting a stochastic background for energies at this lower energy bound.

can be used to establish the inflaton potential amplitude and its first derivative.
Figure 5. Same as Fig. 4, but we show the background at frequencies related to the proposed Big Bang Observer mission. For comparison, we also show the expected stochastic backgrounds from foreground sources such as neutron star-neutron star binaries (e.g., Schneider et al. 2001), white dwarf-white dwarf binaries (e.g., Farmer & Phinney 2003), neutron star-white dwarf binaries (e.g., Cooray 2004d), and the background related to single rotational neutron stars (Ferrari et al. 1999). For a reliable detection of the inflationary gravitational wave signal, the background related to neutron stars must be removed. This can be achieved given the low merger rate of these binaries and the rapid orbital evolution of the binary such that the gravitational wave frequency across this band changes substantially over the observational period.

Combining this information with CMB, at roughly 30 orders of magnitude difference in scales, should provide additional information to reconstruct the shape of the potential. While a priori assumed potential can easily be constrained based on the shape of the potential al, for a general reconstruction of the po-
potential shape, the simple approximations considered in the literature, based on power-law expansions of the potential, however, may not be appropriate given the large difference in scales. A detailed analysis on the extent to which inflation models can be studied with joint constraints between CMB and direct gravitational-wave detections will be discussed elsewhere (Smith et al. 2005).

Acknowledgments: Author thanks Marc Kamionkowski, Mike Kesden, Naoki Seto, Kris Sigurdson, and Tristan Smith for collaborative work. The author especially thanks Tristan Smith for his help with writing review sections related to inflation and the direct detection of inflationary gravitational waves described in figures 4 and 5. This work was supported by the Sherman Fairchild foundation, NASA, and the Department of Energy.
