AIM
To evaluate the inflammatory state in Crohn's disease (CD) patients and correlate it with genetic background and microbial spreading.

METHODS
By means of flow cytometry, production of tumor necrosis factor-alpha (TNF-α) was measured in peripheral blood monocytes from patients suffering from CD, ulcerative colitis (UC) and in healthy subjects after stimulation of the NOD2 and TLR pathways. CD patients were genotyped for the three most common NOD2 variants (R702W, G908R and L1007Pfs*2) and basal production of TNF-α was correlated to NOD2 genotype. Also, production of TNF-α was correlated to plasmatic levels of LPS Binding Protein (LBP), soluble (s) CD14 and to the activity state of the disease.

RESULTS
The patients with CD were characterized by a significantly higher monocyte basal expression of TNF-α.
compared with healthy subjects and UC patients, and after stimulation with Pam3CSK4 (ligand of TLR2/1) and MDP-L18 (ligand of NOD2) this difference was maintained, while other microbial stimuli (LPS, ligand of TLR4 and PolyI:C, ligand of TLR3) induced massive activation in CD monocytes as well as in UC and in healthy control cells. There was no significant difference in the production of TNF-α between patients who carried CD-associated heterozygous or homozygous variants in NOD2 and patients with wild type NOD2 genotype. Although serum LBP levels have been shown to correlate positively with the state of activity of the disease, TNF-α production did not show a clear correlation with either LBP or sCD14 levels in plasma. Moreover, no clear correlation was seen between TNF-α production and activity indices in either CD or UC.

CONCLUSION
Peripheral monocytes from CD express higher basal and stimulated TNF-α than controls, regardless of NOD2 genotype and without a clear correlation with disease activity.

Core tip: Crohn’s disease (CD) is characterized by an aberrant activation of the mucosal immune system in genetically susceptible subjects, who often harbor variants in genes involved in the innate immunity. To study the integrity of innate immune response, the activity of the TLR and NOD2 pathways was investigated, measuring TNF-α expression in peripheral blood monocytes. CD monocytes showed a higher production of TNF-α, which was not clearly related to disease activity, to NOD2 genotype or to the presence of translocated bacteria (indirectly measured by serum LPS-binding protein), indicating that this TNF-α hyperproduction may rely on a NOD2-independent pathway and is not due to systemic exposure to LPS.

INTRODUCTION
Inflammatory bowel diseases (IBD) are complex inflammatory conditions that include different chronic and relapsing intestinal diseases, such as Crohn’s disease (CD) and ulcerative colitis (UC). Both genetic and environmental factors are thought to play a role in determining the disease phenotype.

On the one hand, CD and UC both involve intestinal mucosa and share some clinical symptoms, i.e., bloody diarrhoea, abdominal pain and weight loss. On the other hand, they present peculiar clinical and pathogenic features. Indeed, major differences between the two pathologies are found in the localization of lesions: while CD interests the small intestine (ileum) in particular, UC manifestations are localized mainly in the colon and rectum. Moreover, CD intestinal lesions, differently from UC, cause transmural inflammation and are characterized by skip lesions, alternating inflamed and not inflamed regions.

Diagnosis is based on clinical symptoms and medical history of the patients and then confirmed by endoscopic evaluations and histology. The classification of the disease, which is useful for prognosis and management of patients, is based on index of activity. In particular, the reference scores for pediatric patients is the Pediatric Crohn’s disease Activity Index (PCDAI) and the Pediatric Ulcerative Colitis Activity Index (PUCAI)

The immunopathogenesis underlying CD involves immune cells, such as monocytes, macrophages, neutrophils, recruited and activated via inflammatory cytokines, i.e., interleukin 6, interleukin 10, Interferon-gamma and Tumor Necrosis Factor-alpha (TNF-α) as well as commensal microbiota. In contrast, lymphocytic immune dysregulation seems to play an important role in UC, as shown by the increase of T cells activation markers and cytokines. Several gene variants are associated with the activity of the T cells and with the control of mucosal inflammation.

Although the etiopathology of CD is still unclear, several studies have linked the onset of the disease with an imbalance between mucosal immune system and microbiota. For this reason, it has been suggested that CD inflammation may represent the compensatory response to a variety of minor defects in mucosal innate immunity. These deficiencies may account for changes in the intestinal microbiota (dysbiosis), which, together with multifactorial damages of the intestinal barrier, may facilitate bacterial translocation to the lamina propria and engagement of inflammatory cells. Microbial components from translocated bacteria can reach mesenteric lymph nodes and the bloodstream, making it possible to measure lipopolysaccharide (LPS), LPS-binding Protein (LBP) and soluble (s)CD14, as markers of bacterial spread across the intestinal mucosa. Moreover, the circulating microbial components can induce excessive stimulation of Toll like receptors (TLRs) followed by exacerbated activation of the immune system. It has been proposed that genetic variants in nucleotide oligomerization domain 2 (NOD2), the
first gene associated with IBD,[12-14] may contribute to increasing the risk of disease by interfering with the response of monocytes to bacterial compounds. NOD2 is a cytoplasmic receptor that specifically recognizes muramyl dipeptide (MDP) present on the bacterial wall. It is involved in the regulation of acute inflammation, secreting pro-inflammatory cytokines such as TNF-α.[15]. However, despite the huge amount of research on this topic, it is still not clear how CD-associated NOD2 variants may contribute to the pathogenesis of the disease. On the one hand, dysfunctional pathogen associated molecular patterns (PAMPs) sensing in CD, involving NOD2 and other TLR pathways, could lead to altered shaping of gut microbial species, or dysbiosis.[16-18] On the other hand, NOD2 deficiency could lead to impaired autophagy and inflammation, with excessive response to TLR stimulation[19].

All this considered, a first aim of this study was to evaluate NOD2 and TLR signaling pathway integrity in CD. Immune activation was evaluated in terms of production of TNF-α by peripheral monocytes, since the NOD2 pathway is particularly important in these cells. Moreover, peripheral blood monocytes are good representatives of the innate immune system and can easily be obtained from patients during blood sampling performed for clinical purposes.

CD monocytes were activated with different purified microbial compounds [MDP-L18 (NOD2 ligand), LPS (TLR4 ligand), Pam3CSK4 (TLR2/1 ligand), Poly I:C (TLR3 ligand)]). Production of TNF-α was then evaluated by flow cytometry in comparison with samples from UC and healthy donors. Intracellular production of TNF-α was correlated with the activity state of the disease, with the genotype of the patients and with the levels of plasmatic LBP and sCD14.

As expected, CD patients displayed higher monocyte TNF-α production in basal condition and after stimulation of NOD2 and TLR2/1. Conversely, stimulation of TLR3 and TLR4 induced similar TNF-α production among CD, UC and healthy donors, suggesting that in CD, monocytes might be primed by mycobacterial components that can induce reduced tolerance to PAMPs. Neither the variants in NOD2 susceptibility gene nor the state of activity of the disease (PCDAI score) correlated with intracellular TNF-α. Moreover, the levels of plasmatic LBP, which have been shown to correlate positively with the activity of the disease, did not exhibit a clear correlation with monocyte activation.

MATERIALS AND METHODS

Patient recruitment
Monocytes were obtained from heparinized blood of 38 CD patients, 31 UC patients (diseased controls) and 50 healthy donors (HD; negative controls) subsequent to receiving written consent. All subjects were recruited from the Gastroenterology and Clinical Nutrition Unit of the Institute for Maternal and Child Health IRCCS “Burlo Garofolo”, Trieste, Italy. The IBD patients were classified according to the disease activity evaluated by physician global assessment (based on PCDAI and PUCAI scores).

The present study was approved by the Institutional Review Board of the Institute for Maternal and Child Health “Burlo Garofolo” (RC 03/2009).

Intracellular cytokine staining
This cytometric technique allows for the detection of intracellular TNF-α in monocytes stimulated with synthetic microbial stimuli, to investigate the functionality of the innate immune pathway. The protocol was adapted from Takada et al[20].

Briefly, Peripheral Blood Mononuclear Cells (PBMCs) were isolated from whole heparinized blood by centrifugation on Ficoll separating solution (Lympholite, Cederlane, Burlington, NC, United States) at 500 × g for 30 min at room temperature. 2 × 10⁵ PBMCs were resuspended in 200 µL of culture medium (RPMI, EuroClone, Milan, Italy) supplemented with 10% human AB serum (Sigma Aldrich, Milan, Italy), 2 mM L-glutamine (EuroClone), 100 U/mL penicillin (EuroClone) and 0.1 mg/mL streptomycin (EuroClone) and stimulated with TLR and NOD2 ligands: 100 ng/ml Lipopolysaccharide (LPS; TLR4 ligand, Sigma Aldrich), 10 µg/mL Polyinosinic-polycytidylic acid sodium salt (PolyI:C; TLR3 ligand, Sigma Aldrich), 500 ng/mL L-18 Muramyl DiPeptide (MDP-L18; NOD2 ligand, InvivoGen, San Diego, CA, United States), 500 ng/mL Pam3CSK4 (TLR2/1 ligand, InvivoGen) for an initial period of 30 min at 37 °C, in a CO2 incubator. Subsequently, 10 µg/mL of Brefeldin A (BFA, Sigma Aldrich) were added to inhibit the secretion of newly synthesized cytokines and cells were incubated for additional 3.5 h. BFA, without any stimulus, was added to the unstimulated control tube. After incubation, FITC conjugated anti-CD14 antibody (eBiosciences, San Diego, CA, United States) was added for surface staining to identify monocytes, followed by a fixation step with FACS Permeabilizing Solution (BD Biosciences, San Jose, CA, United States). After centrifugation at 300 × g for 8 min, cells were permeabilized using FACS Permeabilizing Solution 2 (BD Biosciences). PBMCs were washed with Wash Buffer (PBS + 1% BSA + 0.1% NaN₃), and anti-TNF-α PE antibody (BD Biosciences) was added to perform the intracellular staining. A fluorescent-conjugated isotype control antibody was used to detect non-specific bindings (PE IgG Isotype control, BD Biosciences). Finally, after an additional wash, the cells were fixed with PBS + 1% paraformaldehyde for analysis on a flow cytometer. Data were acquired on a CyAn ADP flow cytometer (Beckman Coulter, Fort Collins, CO, United States) and analyzed using FlowJo software v 7.6 (TreeStar, Ashland, OR, United States). Results are expressed as percent of TNF-α positive monocytes, after gating on CD14 positive cells.

NOD2 variant analysis

CD patients were screened using targeted gene sequencing to identify the three principal variants in NOD2 susceptibility gene [c.2104C>T; p.R702W (rs2066844), c.2722G>C; p.G908R (rs2066845) and c.3016_3017insC; p.L1007Pfs*2 (rs2066847)].

DNA samples were collected from patients suffering from CD (n = 36). Genomic DNA of each patient was extracted from 1-2 ml EDTA-anticoagulated blood using the EZ1 DNA Blood Kit (QIAGEN, Valencia, CA, United States) according to the manufacturer's instructions. To analyze the three IBD associated variants in the NOD2 gene (NM_022162), Polymerase chain reaction (PCR) amplification was performed using the KAPA 2G Fast Hot Start ReadyMix (RESNOVA, Rome, Italy). Purified PCR products were directly sequenced in both directions using the amplification primers by the ABI PRISM 3130XL automated DNA Sequencer (Applied Biosystems, United States). Sequences were analyzed using Seqman II Software (DNASTAR I Lasergene Biosystems, United States). Sequences were analyzed by Blast, based on the relative sequence deposited in GeneBank. The specific primers for each variant are summarized in Table 1.

LPS-Binding Protein and soluble CD14 quantification

Samples were collected from patients suffering from CD (n = 27), UC (n = 22) and from healthy individuals (n = 36). Plasma samples were obtained by centrifuging heparinized blood at 1300 × g for 10 min and were stored at -80 °C until LBP and sCD14 levels were measured.

Quantifications were performed using the LPS-binding Protein (Human) ELISA kit (Abnova, Taipei City, Taiwan) and the human CD14 ELISA kit (RayBio, Norcross GA, United States), following the manufacturer's instructions.

Absorptions were measured at 450 nm with a GloMax®-Multi+ Microplate Multimode Reader (Promega Corporation, Madison, United States). The concentration of each sample was calculated from the standard curve, obtained by plotting absorbance vs known standard concentrations.

Table 1 Characteristics of Inflammatory bowel diseases patients included in the study

| Patients (n = 69) | Age (yr) (mean ± SD) | Male/female | Active/remission |
|-----------------|---------------------|-------------|------------------|
| CD (n = 38)     | 12 ± 4.47           | 25/13       | 18/20            |
| UC (n = 31)     | 13 ± 5.13           | 15/16       | 19/12            |

CD: Crohn’s disease; UC: Ulcerative colitis.

Statistical analysis

All statistical analyses were performed using GraphPad Prism software version 5 (GraphPad, SanDiego, United States).

Monocyte intracellular TNF-α expression

To study the production of TNF-α by monocytes, cells were isolated from peripheral blood of patients with CD and UC and of healthy donors (HD). Monocytes were stimulated with TLR and NOD2 purified stimuli: LPS (TLR4 ligand), Pam3CSK4 (TLR2/1 ligand), Poly I:C (TLR3 ligand) and MDP-L18 (NOD2 ligand). TNF-α expression in monocytes was analyzed by flow cytometry after gating on CD14 positive cells.

Results

The clinical characteristics of all the patients included in the study are presented in Supplementary Table 1 and summarized in Table 1.

Monocyte intracellular TNF-α expression

To study the production of TNF-α by monocytes, cells were isolated from peripheral blood of patients with CD and UC and of healthy donors (HD). Monocytes were stimulated with TLR and NOD2 purified stimuli: LPS (TLR4 ligand), Pam3CSK4 (TLR2/1 ligand), Poly I:C (TLR3 ligand) and MDP-L18 (NOD2 ligand). TNF-α expression in monocytes was analyzed by flow cytometry after gating on CD14 positive cells.

RESULTS

The clinical characteristics of all the patients included in the study are presented in Supplementary Table 1 and summarized in Table 1.

TNF-α expression and NOD2 genotype

A genetic survey was carried out on 36 available patients with CD (out of 38).PCR and DNA sequencing analyses revealed that 13 patients were homozygous or heterozygous for one or more of the three CD-associated genetic variants in NOD2 (Table 2). The remaining 23 patients were found to be wild type for the three polymorphisms (Supplementary Table 1).
After grouping CD patients based on NOD2 genotype, no significant differences in TNF-α positive monocytes were detected between patients with wild type or mutated genotype (CD WT: 14.87 ± 3.1 vs CD Mut 13.82 ± 4.5) (Figure 2). Data regarding the single NOD2 variants are shown in Supplementary Figure 1.

**TNF-α expression and disease activity index**

Intracellular production of TNF-α by monocytes from CD and UC patients was correlated to the disease activity score, expressed as PCDAI (Pediatric Crohn's Disease Activity Index) or PUCAI (Pediatric Ulcerative Colitis Activity Index). No correlation between the two parameters was found, either in CD (R^2 = 0.004) or in UC (R^2 = 0.01) subjects (Figure 3).

**TNF-α expression and LBP and sCD14 levels**

Plasmatic levels of LBP and sCD14 were measured to verify if the basal inflammatory state in CD patients could be due to exposition of monocytes to microbial components in peripheral blood.

Levels of LBP were higher in plasma from patients with CD compared to HD [(median CD 19.11 (16.35-21.89), HD 15.01 (11.85-18.84), P < 0.05)] (Figure 4A) and this condition was noticed also when patients were grouped by disease activity [(median activeCD: 20.44 (16.81-26.31) vs HD: 15.01 (11.85-18.84); P < 0.05)] (Figure 4B); furthermore a significant difference was also found...
between UC in active or remissive phase [(median UC: 20.74 (14.55-21.57) vs rUC: 12.35 (8.35-13.5); P < 0.05)] (Figure 4B).

LBP values displayed a significant correlation with the disease activity index, especially for CD ($R^2 = 0.40$, $P < 0.001$) (Figure 4C and D). However, there was no correlation between monocyte TNF-α expression in basal condition and plasmatic levels of LBP in any of the analyzed groups (CD: $R^2 = 0.04$, UC: $R^2 = 0.0004$, HD: $R^2 = 0.005$) (Figure 5).

The quantification of sCD14 was not significantly different among the three groups and did not correlate with the degree of monocyte activation in CD (data not shown).

**DISCUSSION**

The activation of the innate immune system is thought to play a pivotal role in the pathogenesis of CD. Most genetic variants associated with the disease involve genes that are expressed in monocytes and that contribute to functional innate response to microbes. For example, *NOD2* and *ATG16L1* are involved in the response to molecular patterns associated with pathogens (PAMPs) and in autophagy, a process that can amplify the inflammatory response to phagocytized materials. Notably, there is a number of genes and processes involved in phagocytic function and innate immunity that have been shown to be responsible for rare monogenic forms of Crohn’s-like intestinal inflammation. For instance, early onset CD-like inflammatory bowel disease has been described in neutropenias and in functional deficiencies of phagocytes, such as chronic granulomatous disease and leukocyte adhesion deficiency, as well as in defects of other genes interacting with the NOD2 pathway of response to PAMPs, such as XIAP[8,21]. These findings have raised the question of whether CD should be considered more like an immunodeficiency than an autoinflammatory condition[22-24].
For this reason, several studies have investigated the function of peripheral blood monocytes, an easily available sample cell that can be, at least in part, representative of the innate immune profile of CD. The observation of impaired monocyte/macrophage function against yeast particles dates back decades [25]. However, it is still not clear whether these defects are a cause or a consequence of CD inflammation. For example, it has been hypothesized that CD-associated monocytes may display hyporesponsiveness because of massive mucosal stimulation [26]. Indeed, we and other groups have demonstrated that peripheral blood monocytes from CD show an increased expression of activation markers [27-29], whilst ex-vivo maturation of dendritic cells may be somehow impaired [30]. Overall, these results have highlighted the paradox of defective and excessive immunities in CD [31]: CD monocytes display increased activation and production of inflammatory cytokines, but they may present functional defects in terms of capacity to mature effectively and to clear bacteria efficiently [32]. Indeed, the depletion of monocytes could improve the response to anti-inflammatory treatments in CD [33]. Thus, the contribution of monocytes to the pathogenesis of CD seems to be quite complex, involving hyper-activation and defective functionality at the same time. 

Beynon et al [34] demonstrated that in spite of increased basal activation, CD-associated monocytes display reduced response to MDP stimulation, in a manner that greatly depends on NOD2 genotype. The effect of NOD2 variants on the activation of monocytes has been confirmed by other studies showing that homozygous mutations can almost abrogate TNF-α production after MDP stimulation [35]. However, NOD2 defects can also impair MDP-induced tolerance, resulting in sustained monocyte activation and TNF-α production [36].

The aim of our research was the analysis of the integrity of the different pathways of the innate immune network. By means of a cytometric protocol, adapted from a clinically oriented technique already used for the screening of some primary immunodeficiency [20], we analysed the production of TNF-α triggered in monocytes by different stimuli, to depict possible alterations in different pathways of innate immunity to PAMPs. 

We demonstrated that peripheral monocytes from CD show significant basal production of TNF-α, and that this is not clearly related to either the disease activity or the NOD2 genotype, supporting the idea that, in these cases, hyper-production of TNF-α relies on NOD2-independent pathways. Indeed, stimulation with

**Figure 4** Dosage of LPS-binding protein and correlation with disease activity index. A, B: Quantification of plasmatic LPS-Binding Protein (LBP) from patients affected by active Crohn’s disease (CD), remisive Crohn’s disease (rCD), active Ulcerative Colitis (UC), remisive Ulcerative Colitis (rUC) and healthy donors (HD). Data are represented with box plots using Tukey’s whiskers. Statistical significance is denoted by letters (P < 0.05); C, D: Correlation between activity Index, expressed by PCDAI (Pediatric Crohn’s Disease Activity Index) or PUCAI (Pediatric Ulcerative Colitis Activity Index) with plasmatic level of LBP in patients with Crohn’s disease (CD) (C, R² = 0.40) or Ulcerative Colitis (UC) (D, R² = 0.28). The squared Pearson correlation coefficients (R²) and the P value are shown.
MDP or with Pam3CSK4 led to higher TNF-α production in CD patients than in controls. The stronger response in CD after the stimulation with the NOD2 ligand did not find a clear explanation, but it highlights the importance of NOD2 signalling in CD and not in UC. This result is coherent with the knowledge that NOD2 is the main genetic factor associated with CD, even though the mechanisms underlying the pathogenesis of the disease remain controversial.

Thus, the activation of monocytes resulting from the mucosal immunopathology of CD could play a greater role in inducing TNF-α than the NOD2 genotype, not only in the intestinal mucosa but also in peripheral blood. A possible hypothesis is that excessive activation of monocytes occurs in response to bacterial translocation across the epithelium and to minor defects in bacterial clearance or in MDP-induced tolerance. Notably, the paradoxical efficacy of GM-CSF in some cases of CD may be due to the correction of such defects in epithelial monocytes, for example by rescuing their epithelial repair function. Another critical function for mucosal monocytes may concern the induction of antimicrobial peptide production by Paneth cells; indeed, a defective production of defensins after bacterial translocation may result in altered shaping of gut microbiota, leading to inflammatory amplification in a vicious circle.

We investigated whether increased activation of peripheral monocytes correlated with plasma levels of LPS-binding protein (LBP). We showed that plasma concentrations of LBP correlate positively with disease activity, both in CD and in UC, in agreement with previous studies. However, there was no significant correlation between LBP levels and activation of peripheral monocytes, suggesting that monocytes are not activated by systemic exposure to LPS. We cannot, however, rule out the existence of other bacterial molecular patterns.

An added value of our research is that we studied monocyte function after stimulation of different TLR pathways. Several studies have already reported that altered patterns of TLR expression can be differentially found in CD, rather than in UC, even though no definitive association between the pathway dysregulations and the disease phenotypes has been ever identified. We interestingly found that peripheral blood monocytes from CD patients displayed increased response to Pam3CSK4, which is a mycobacterial-like ligand for TLR2/1. The increased response to Pam3CSK4 was quite specific to CD monocytes and was not found in UC. Thus, it is unlikely that the hyper-response to TLR2/1 signaling depended on monocyte activation alone. A possible explanation is that peripheral monocytes from patients with CD are primed by mycobacterial components released in the intestinal mucosa, maybe as a result of colonization with bacteria such as mycobacterium avium paratuberculosis (MAP). The presence of MAP in CD intestinal mucosa and bloodstream has been proved by several works and accomplished by different techniques; it has been repetitively associated with the pathogenesis of CD but its role in the etiology remains to be defined. Our results should prompt further investigation on the immune response to MAP in healthy population and in CD.

In conclusion, we showed that peripheral monocytes from patients with CD have higher basal

**Figure 5** Correlation of monocyte tumor necrosis factor-alpha expression and LPS-binding protein levels in inflammatory bowel disease patients.
Correlation between monocyte expression of tumor necrosis factor-alpha (TNF-α) and plasmatic level of LBP in patients affected by Crohn’s disease (CD) or ulcerative colitis (UC) and in healthy subjects (HD). The squared Pearson correlation coefficients (R²) are shown. No statistical significances were found.
production of TNF-α than controls, regardless of NOD2 genotype and without a clear correlation with disease activity. Moreover, peripheral monocyte activation does not seem to be due to plasma exposition to LPS. There is also an increased response of monocytes to MDP or Pam3CSK4 stimulation, which could reflect a reduced tolerance to bacterial PAMPs. Based on these data, it is worth investigating the possible priming of monocytes by mycobacterial colonization, for example with MAP.
