ABSTRACT

We report the discovery of a Type IIn supernova (SN) in the low-metallicity dwarf galaxy J1320+2155, with an oxygen abundance 12 + log O/H = 8.0 ± 0.2. This finding is based on Sloan Digital Sky Survey (SDSS; York et al. 2000) and 3.5 m Apache Point Observatory (2009 February) spectra taken one year apart, and on the observations that: the Hβ and Hα emission lines show broad components corresponding to gas expansion velocities of ∼1600 km s⁻¹; the Balmer decrement is exceedingly high: the Hα/Hβ flux ratio, being more than 30, implies a very dense environment (>10⁷ cm⁻³); and the Hα broad luminosity decreases slowly, by only a factor of ∼1.8 over the course of a year, typical of the slow luminosity evolution of a Type IIn SN. Several weak coronal lines of [Fe vii] and [Fe x] are also seen in the SDSS spectrum, implying ionization of the pre-shock circumstellar medium by shock-induced X-ray emission. The galaxy J1320+2155 is the first dwarf system ever to be discovered with a Type IIn SN exhibiting coronal lines in its spectrum.

Key words: galaxies: abundances – galaxies: irregular – galaxies: ISM – supernovae: general

1. INTRODUCTION

During the last few years, we have been carrying out a systematic search for very metal-deficient emission-line galaxies in the Sloan Digital Sky Survey (SDSS; York et al. 2000). The selection criteria and the first results of that search are given in Izotov & Thuan (2007, 2008, 2009) and Izotov et al. (2007). In the course of this study, we have focused in particular our attention on a small subset of these galaxies, those with spectra that exhibit broad components in their strong emission lines, mainly in Hβ, [O iii] λλ4959, 5007, and Hα. Izotov et al. (2007) have found that the most plausible origin of broad-line emission for the majority of galaxies is the evolution of massive stars and their interaction with the circumstellar and interstellar medium. Broad emission with Hα luminosities in the range from 10⁶ erg s⁻¹ to 10⁹ erg s⁻¹ is most likely produced in circumstellar envelopes around hot Ofp/WN9 and/or LBV stars (Izotov & Thuan 2009). However, there is a handful of galaxies with broad Hα luminosities that can be as high as 10⁴⁰–10⁴² erg s⁻¹. They probably arise from Type IIp or IIn supernovae (SNe) or from active galactic nuclei (AGNs) containing intermediate-mass black holes (Izotov & Thuan 2008).

We report here the discovery of a SN in the dwarf emission-line galaxy J1320+2155, based on a spectrum in the Data Release 7 (DR7) of the SDSS that became publicly available in 2008 November. The general characteristics of the galaxy are shown in Table 1. The distance to the galaxy is D = 92 Mpc, as inferred from its redshift and adopting a Hubble constant H₀ = 75 km s⁻¹ Mpc⁻¹. At this distance, the absolute SDSS g-band magnitude of the galaxy is −16.89, which qualifies it as a dwarf galaxy. In the SDSS image obtained on 2005 March 12 (Figure 1), the galaxy shows a compact elongated shape, with an angular size of ∼3.3 arcmin (FWHM) that corresponds to a linear size of ∼1.5 kpc. Its colors (u − g = 0.76, g − r = 0.38, and g − i = 0.51) are typical of dwarf irregular galaxies.

The SDSS spectrum of J1320+2155, obtained on 2008 February 11 (Figure 2), reduced to zero redshift, shows a Hβ emission line that has a broad width (∼1400 km s⁻¹), and a considerably more intense Hα emission line, also with a broad width (∼1700 km s⁻¹). These broad features are very unusual for the spectrum of a dwarf emission-line galaxy. To better understand their origin, we have obtained new high- and low-resolution spectroscopic observations of J1320+2155. Together with the SDSS spectrum, these new observations will allow us to study the temporal evolution of the broad-line features and constrain their origin: are they due to an AGN or to a luminous SN?

In Section 2, we describe the new spectroscopic observations and data reduction. Section 3 discusses the physical properties of the SDSS and new spectra and Section 4 summarizes our findings.

2. OBSERVATIONS AND DATA REDUCTION

We have obtained new optical spectra of the emission-line dwarf galaxy J1320+2155 on the night of 2009 February 23, using the 3.5 m Apache Point Observatory (APO) telescope. These new spectra allow us first to study the temporal variations of the Hβ and Hα emission lines, and second to detect the [O ii] λ3727 emission line needed for an accurate determination of the oxygen abundance in the galaxy. This line is absent in the SDSS spectrum (Figure 2) because of the galaxy’s low redshift (z = 0.023): the [O ii] line is not redshifted enough to fall in the wavelength range covered by the SDSS spectra. The APO observations were made with the Dual Imaging Spectrograph (DIS) in both the blue and red wavelength ranges. Two different sets of gratings were used for the low- and high-spectral resolution observations. For the low-resolution observations in the blue range, we use the B400 grating with a linear dispersion of 1.83 Å pixel⁻¹ and a central wavelength of 4400 Å, while in the red range we use the R300 grating with a linear dispersion of 2.31 Å pixel⁻¹ and a central wavelength of 7500 Å. The above instrumental setup gave a spatial scale of 1.5 arcsec pixel⁻¹.
along the slit of 0′.4 pixel\(^{-1}\), a spectral range \(\sim\)3600–9600 Å and a spectral resolution of 7 Å FWHM. For the high-resolution observations, we use in the blue range the B1200 grating with a linear dispersion of 0.62 Å pixel\(^{-1}\) and a spectral resolution of 7 Å FWHM. For the high-resolution APO spectrum shows that the broad component of both the H\(\beta\) and H\(\alpha\) emission lines is slightly asymmetric and blueshifted (by \(\sim\)200 km s\(^{-1}\)) with respect to the narrow component.

The SDSS spectrum (Figure 2), obtained with an exposure time of 3000 s, exhibits some unusual emission lines that are atypical of dwarf emission-line galaxies. In addition to the broad H\(\beta\) and H\(\alpha\) emission lines, other permitted lines, He i \(\lambda\)4471, \(\lambda\)5876, \(\lambda\)6678, \(\lambda\)7065, and O i \(\lambda\)8445 also show a broad component. Furthermore, several narrow high-ionization coronal lines such as [Fe vii] and [Fe x] lines are detected, implying an extremely high electron temperature of the regions where they originate. The 3.5 m APO spectra were obtained with shorter exposure times, so do not show the high-ionization coronal lines. Furthermore, they were obtained in non-photometric conditions. To put the APO spectra on a photometric scale, we adjust the flux of its narrow H\(\alpha\) emission line to be equal to that in the SDSS spectrum.

The extinction-corrected nebular line fluxes \(F(\lambda)\) for the SDSS spectrum, normalized to \(I(H\beta)\) and multiplied by a factor of 100, and their errors, are given in Table 2. They were measured using the IRAF SPLOT routine. The listed line flux errors include statistical errors derived with SPLOT from non-flux-calibrated spectra, in addition to errors introduced in the standard star absolute flux calibration, which we set to be 1% of the line fluxes. Data for two additional emission lines were available from the 3.5 m APO spectra. The flux of the [O iii] \(\lambda\)3727 emission line was measured in the low-resolution spectrum. The [N ii] \(\lambda\)6583 emission line is blended with the broad H\(\alpha\) in the SDSS spectrum (inset (b) in Figure 2) but is well separated from the broad H\(\alpha\) in the high-resolution 3.5 m APO spectrum (Figure 3(b)), allowing a measurement of its flux. All narrow lines, including the hydrogen lines, have widths of 2–3 Å FWHM: they are thus unresolved.

It is seen from Table 2 that the observed fluxes \(F\) of the hydrogen emission lines relative to the H\(\beta\) flux are very close to their recombination values, for an electron temperature of \(\sim\)10,000 K. This suggests that the narrow hydrogen lines arise in an ionized interstellar medium with a number density \(<10^7\) cm\(^{-3}\). Adopting an electron temperature of 10,000 K, we correct the narrow line fluxes for both reddening (using the extinction curve of Whitford 1958) and underlying hydrogen stellar absorption, derived simultaneously by an iterative procedure as described in Izotov et al. (1994). The extinction coefficient is defined as \(C(H\beta) = 1.47E(B-V)\), where \(E(B-V) = A(V)/3.2\) and \(A(V)\) is the extinction in the V band (Aller 1984). The extinction coefficient \(C(H\beta)\), observed flux \(F(H\beta)\), equivalent width EW(H\(\beta\)), and equivalent width EW(abs) of the hydrogen absorption stellar lines are also given in Table 2.
Figure 2. SDSS spectrum of J1320+2155 obtained on 2008 February 11. The two insets show blow-up spectra of the H\(\beta\) (a) and H\(\alpha\) (b) emission lines.

3. RESULTS

3.1. Variability of the Broad $H\alpha$ Luminosity

The most notable features in the spectra of J1320+2155 are the strong and relatively broad $H\alpha$ and H$\beta$ emission lines. The parameters of these lines are shown in Table 3 for both the SDSS and high-resolution 3.5 m APO spectra. Examination of Table 3 shows a striking fact: the $H\alpha$ to H$\beta$ flux ratio is exceedingly high, being greater than 30, more than 1 order of magnitude greater than its recombination value. This implies that the broad hydrogen emission comes from a high-density gas with an electron density in excess of $10^7 \text{cm}^{-3}$. The large intensity of $H\alpha$ relative to H$\beta$ is due to electron collisional excitation in a very dense environment. The $H\alpha$ luminosity derived from the SDSS spectrum has the high value $L(H\beta) = 6.43 \times 10^{40} \text{erg s}^{-1}$. As discussed by Izotov & Thuan (2008), such a high luminosity can be explained by the presence in the dwarf galaxy of either an AGN or a Type IIP or Type IIn SN. Thanks to the APO spectra taken about one year after the SDSS spectrum, we can ascertain that the broad $H\alpha$ luminosity has decreased by a factor of $\sim 1.8$ during that period. This drop in luminosity implies that the $H\alpha$ emission is produced by an expanding SN envelope. We would expect a roughly constant luminosity in the case of an AGN and a more rapid fading in the case of a Type IIP SN.

3.2. A Type IIn Supernova

We have no photometric observations of the SN. We have therefore estimated its brightness from the continuum level of the SDSS spectrum obtained on 2008 February 11. In the wavelength range of $\sim 4300–4500 \text{Å}$ which corresponds to the g filter, we obtain $g \sim 17.6$ or about 0.3 mag brighter than the g magnitude of J1320+1505 before the SN explosion, as derived from the SDSS $g$ image obtained on 2005 March 12 (Table 1). Thus, the absolute $g$ magnitude of the SN on the date of the SDSS spectral observations was $\sim -15.6$, as compared to the absolute $g$ magnitude of $\sim -16.9$ of the galaxy before the SN event. The broad $H\alpha$ and continuum flux distributions along the slit, peak at the same location in the 3.5 m APO high-resolution spectrum, in the central part of the galaxy. This implies that the SN is located in the nucleus of the dwarf galaxy. Note that the continuum level near $H\alpha$ did not change over a period of one year, the time interval between the SDSS and APO observations. The constancy of the continuum level, the slow decline of the $H\alpha$ luminosity, and a nearly constant expansion velocity of $\sim 1600 \text{km s}^{-1}$ as measured from the FWHM of the broad component of the $H\alpha$ emission line, are all characteristics of a Type IIn SN (SN 1988Z, Statnikov & Sadler 1991; Turatto et al. 1993; Salamanca et al. 2002; SN 1995N, Fransson et al. 2002; SN 1997eg, Hoffman et al. 2008; SN 2005ip, Smith et al. 2009; SN 2007rt, Trundle et al. 2009).

3.3. Other Lines with Broad Components

Besides the $H\alpha$ and H$\beta$ lines, the He i λ5876, λ6678, and λ7065 emission lines in the SDSS spectrum also show narrow and broad components. We use Gaussian profiles to fit both components. The narrow components fluxes of these lines are given in Table 2. They show a striking fact: depending on the line, they are larger by a factor 1.5–5 than the fluxes expected in a low-density ionized gas. This suggests a relatively dense environment in which the narrow He i lines are considerably enhanced by collisions in a dense pre-shock region of the SN.

The fluxes relative to the broad H$\beta$ flux and widths of the He i broad components are given in Table 4. The broad component of the He i lines is also collisionally enhanced, but to a larger

Table 3

| Telescope | Date       | Flux$^a$ | H$\beta$ Luminosity (erg s$^{-1}$) | FWHM (km s$^{-1}$) | Flux$^a$ | H$\alpha$ Luminosity (erg s$^{-1}$) | FWHM (km s$^{-1}$) |
|-----------|------------|----------|----------------------------------|------------------|----------|-----------------------------------|------------------|
| SDSS      | 2008 Feb 11| 2.09 ± 0.32 | 2.12 ± 0.32 × 10$^{39}$ | 1438 ± 271 | 63.55 ± 1.06 | 6.43 ± 0.11 × 10$^{40}$ | 1659 ± 22 |
| 3.5 m APO | 2009 Feb 23| 0.78 ± 0.12 | 0.79 ± 0.12 × 10$^{39}$ | 1663 ± 310 | 35.56 ± 0.85 | 3.59 ± 0.09 × 10$^{40}$ | 1596 ± 15 |

Note. $^a$ In $10^{-15} \text{erg s}^{-1} \text{cm}^{-2}$.
The errors to the widths of the broad hydrogen lines. These errors of their fluxes and widths are consequently larger. The electron temperature $T_e$ originates from larger density regions. In addition, a broad $\text{O}^\text{iii}$ line at 5007 Å compared to the narrow component, implying that they fluxes that are significantly smaller than the broad $\text{H}\beta$ line flux. The errors of their fluxes and widths are consequently larger. Examination of Table 4 shows that the collisionally enhanced $\text{He}^\text{i}$ lines have widths that are lower but comparable within the errors to the widths of the broad hydrogen lines. These broad lines originate presumably in the post-shock circumstellar medium of the SN.

### 3.4. Ionized Gas Diagnostics from Nebular and Auroral Lines

Narrow nebular and auroral emission lines are frequently used for ionized gas diagnostics and for the determination of the electron temperature $T_e$, the electron number density $N_e$, and the element abundances in $\text{H}^\text{II}$ regions of dwarf emission-line galaxies. Applying the procedures of, e.g., Izotov et al. (2006) and the semiempirical method described by Izotov & Thuan (2007), based on the fluxes of the strong nebular $\text{O}^\text{iii}$ $\lambda3727$, $\text{[N}^\text{ii}] \lambda4959, 5007$ emission lines, we derive an oxygen abundance $12 + \log O/H = 7.68$ for the ionized gas in J1320+2155. However, this technique is applicable only in the case of a low-density gas ionized by stellar radiation. Usually, the electron density in the $\text{H}^\text{II}$ region is derived from the nebular $\text{S}^\text{ii}$ $\lambda6717/\lambda6731$ line ratio. For J1320+2155, this ratio is high, $>1$, suggesting a low electron number density of the order of a few hundred cm$^{-3}$ (Aller 1984). However, as discussed above, there are indications that the narrow line-emitting region in J1320+2155 has a high-density (for example, the narrow $\text{He}^\text{i}$ emission lines are significantly enhanced by collisions), so that the low-density assumption for abundance determinations is not valid. Additionally, the $\text{[O}^\text{iii}] \lambda4363$ and $\text{[N}^\text{ii}] \lambda5755$ auroral lines are relatively strong as compared to the nebular $\text{[O}^\text{iii}] \lambda5007$ and $\text{[N}^\text{ii}] \lambda6583$ emission lines. These lines are used for the determination of the electron temperature in $\text{H}^\text{II}$ regions. Assuming a low density (100 cm$^{-3}$), we derive an electron temperature of $\sim32,500$ K from the $\text{[O}^\text{iii}] \lambda4363/\lambda4959+\lambda5007$ flux ratio. As for the $\text{[N}^\text{ii}] \lambda5755/\lambda6583$ flux ratio, its value is so high that it cannot be explained by any temperature in the low-density regime. Evidently, the regions that are emitting $\text{[O}^\text{iii}]$ and $\text{[N}^\text{ii}]$ are so dense that collisional deexcitation becomes important. This leads to an overestimate of the electron temperature and an underestimate of the abundances if a low density is assumed. Apparently, these lines are emitted in the SN pre-shock dense circumstellar region.

Since the critical densities for collisional deexcitation are significantly higher for auroral lines than for nebular lines, their emission comes preferentially from denser regions as compared to the emission of nebular lines. This fact may explain the apparent disagreement with the low density obtained from the low-ionization nebular $\text{[S}^\text{ii}]$ lines for which critical densities are low ($\sim10^4$ cm$^{-3}$): these originate mainly in low-density regions.

We can estimate the electron number density by using the auroral-to-nebular flux ratios for the $\text{[O}^\text{iii}]$ and $\text{[N}^\text{ii}]$ emission lines and the equations from Aller (1984) for temperature determination. These equations take into account collisional deexcitation. We find that for a reasonable range of temperatures, those varying between 10,000 K and 15,000 K, the electron number density must be in the range $10^4$ cm$^{-3}$ to account for the observed $\text{[O}^\text{iii}] \lambda4363/\lambda4959+\lambda5007$ and $\text{[N}^\text{ii}] \lambda5755/\lambda6583$ flux ratios.

In such dense regions, element abundances cannot be derived because of the unknown spatial distribution of the gas density. We can obtain an estimate of the oxygen abundance of J1320+2155 by using the statistical luminosity–metallicity relation for dwarf irregular galaxies, e.g., the ones by Richer & McCaill (1995) and Skillman et al. (1989). We find $12 + \log O/H = 8.0 \pm 0.2$, higher (by 0.3 dex) than the value obtained by the semiempirical method, as expected because of the high density.

### 3.5. Coronal Lines and Diagnostics of High-ionization Regions

The SDSS spectrum of J1320+2155 exhibits several narrow high-ionization coronal lines of $\text{[Fe}^\text{vii}]$ and $\text{[Fe}^\text{x}]$ (Figure 2). These lines have been seen before in spectra of Type IIn SNe (SN 1988Z, Turatto et al. 1993; Salamanca et al. 2002; SN 1995N, Fransson et al. 2002; SN 1997eg, Hoffman et al. 2008; SN 2005ip, Smith et al. 2009; SN 2007rt, Trundle et al. 2009) in spiral galaxies. However, their occurrence is very rare. J1320+2155 is the first compact dwarf galaxy discovered with a Type IIn SN spectrum showing coronal lines. If collisional ionization is the dominant mechanism, then the presence of these lines implies substantial amounts of gas at temperatures from several $10^5$ K to $\sim10^6$ K (Bryans et al. 2009) and pre-shock ionization of the circumstellar medium by X-ray emission. The gas can be cooler if photoionization is the main mechanism.

The critical densities for coronal lines are $\sim10^8$ cm$^{-3}$ (Nussbaumer & Storey 1982), considerably higher than those for nebular lines of low-ionization species. The coronal lines can act thus as diagnostics of much hotter and denser gas in the SN circumstellar medium. In particular, the observed $\text{[Fe}^\text{vii}] \lambda3759/\lambda6087$ flux ratio of $\sim1.5$ yields densities $<10^5$ cm$^{-3}$ for temperatures above $\sim100,000$ K (Nussbaumer & Storey 1982). The high $\text{[Fe}^\text{vii}] \lambda5159/\lambda6087$ flux ratio also implies that the electron density in the hottest regions is in the range $<10^7$ cm$^{-3}$. This range of number densities is broadly consistent with our estimates from the auroral-to-nebular flux ratios for the lower ionization species. It is also in the range of number densities obtained by Smith et al. (2009) for SN 2005ip, the SN with the spectrum richest in coronal lines known to date, and taken several hundred days after the explosion.

### 4. Conclusions

We present SDSS (2008 February 11) and 3.5 m APO (2009 February 23) spectra of a newly discovered Type IIn SN in the compact dwarf galaxy J1320+2155.

We have obtained the following results.

1. The SN was not present in the SDSS image obtained in 2005 March. The host dwarf galaxy J1320+2155 on that image exhibits a compact regular morphology with a size of $\sim1.5$ kpc and an absolute SDSS g magnitude of $-16.89$, for a distance of 92 Mpc. Its colors are typical of dwarf irregular galaxies.
galaxies. The oxygen abundance of the galaxy, estimated from the luminosity–metallicity relation for dwarf irregular galaxies, is $12 + \log \frac{O}{H} = 8.0 \pm 0.2$.

2. From the light distribution in the slit, we infer that the SN, which appeared prior to 2008 February 11, is in the central part of the galaxy. The broad widths of the $H\alpha$ and $H\beta$ emission lines, corresponding to velocities of $\sim 1600$ km s$^{-1}$ FWHM, an exceedingly high Balmer decrement (a $H\alpha/H\beta$ flux ratio $> 30$), the slow decline of the $H\alpha$ broad luminosity over a timescale of $\sim 1$ year, all point to a Type IIn SN. The spectrum also shows helium lines that are broadened with velocities of $\sim 1000$ km s$^{-1}$ and that are collisionally enhanced.

3. Several narrow auroral and nebular emission lines of different low-ionization species are present in the SDSS spectrum. The auroral-to-nebular line flux ratios suggest that they originate in a dense ($\sim 10^6$ cm$^{-3}$) pre-shock circumstellar region.

4. Several narrow coronal emission lines of $[\text{Fe} \, \text{vii}]$ and $[\text{Fe} \, \text{x}]$ are detected in the SDSS spectrum, implying ionization of the pre-shock circumstellar medium by shock-induced X-ray emission.

There are reasons to suggest that Type IIn SNe may occur in low-metallicity dwarf galaxies. The low metallicity leads to less cooling of the gas and hence to the formation of the more massive stars that are progenitors of this type of SNe. We plan more observations of the SN in J1320+2155 to further constrain its properties.

We thank Roger Chevalier for useful discussions. Y.I.I. thanks the hospitality of the Astronomy Department of the University of Virginia. Support for this work is provided by NASA through contract 1263707 issued by JPL/Caltech. Funding for the Sloan Digital Sky Survey (SDSS) and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, and the Max Planck Society, and the Higher Education Funding Council for England.

Note added in proof. Following the posting of our paper on astro-ph, A. J. Drake from the Caltech Center for Advanced Computing Research (CACR) extracted the light curve of J1320+2155, using data from the Catalina Real-time Transient Survey (CRTS). The light curve can be seen at: http://crts.caltech.edu/J1320+2155.html. This shows that the supernova in J1320+2155 occurred between 2006 January 1 and 2006 February 1. The galaxy brightened by 1.6 mag, reaching a peak $M(V)$ of about $-18.5$ mag. There is then a steep drop-off by about 1.3 mag during 4 months, followed by a more gradual dimming by about 0.2 mag between 2006 June and 2009 July.
