ABSTRACT

We report the observation in the GeV band of the blazar 1ES 0229+200, which over recent years has become one of the primary sources used to put constraints on the extragalactic background light (EBL) and extragalactic magnetic field (EGMF). We derive constraints on both the EBL and EGMF from the combined Fermi–HESS data set taking into account the direct and cascade components of the source spectrum. We show that the limit on the EBL depends on the EGMF strength and vice versa. In particular, an EBL density twice as high as that derived by Franceschini et al. in 2008 is allowed if the EGMF is strong enough. On the other hand, an EGMF strength as low as $6 \times 10^{-18}$ G is allowed if the EBL density is at the level of the lower bound from the direct source counts. We present the combined EBL and EGMF limits as an exclusion plot in two-dimensional parameter space: EGMF strength versus EBL density.

Key words: BL Lacertae objects: individual (1ES 0229+200) – cosmic background radiation – galaxies: magnetic fields

1. INTRODUCTION

Very high energy (VHE) γ-ray flux from distant blazars is absorbed on the way from the source to the Earth through its interaction with the extragalactic background light (EBL) photons. The measurement of the induced distortions of the VHE γ-ray flux from distant hard-spectrum blazars by the effect of absorption on the EBL was used to derive constraints on the EBL density (Aharonian et al. 2006, 2007; Orr et al. 2011).

The conventional derivation of the upper bound on the EBL from γ-ray observations adopts the assumption that the intrinsic power-law-type spectrum of the primary source (a distant blazar) is characterized by the slope $dNγ/dE ≈ E^{−Γ}$ with $Γ ≥ 1.5$. This assumption appears reasonable in the framework of the most simple synchrotron self-Compton (SSC) models for the broadband spectra of blazars. However, particular blazars considered for the derivations of EBL limits (the blazars with hardest intrinsic γ-ray spectra) may not well fit into this simplest SSC model framework, so that the assumption of $Γ ≥ 1.5$ might not be applicable (Aharonian et al. 2008; Katarzynski et al. 2006; Böttcher et al. 2008; Neronov et al. 2011; Lefa et al. 2011a, 2011b). If the intrinsic spectra of the blazars used for the derivation of the upper bound on the EBL density are harder than $Γ = 1.5$, this upper limit is relaxed (Mazin & Raue 2007).

Constraints on the intrinsic slope of the spectra of blazars can be obtained from the observations by the Fermi Large Area Telescope (LAT; Atwood et al. 2009) in the energy band below $≈100$ GeV, where the effect of absorption on the EBL becomes negligible. However, the blazars used for the derivation of constraints on the EBL are characterized by hard spectra, which makes it difficult to observe their flux below 100 GeV. In fact, the blazar 1ES 0229+200, which provides the tightest constraints on the EBL (Aharonian et al. 2007), is not listed in the catalog of sources detected by LAT in two-year exposure (Abdo et al. 2011), with only upper limits on the source flux derived from the LAT data (Neronov & Vovk 2010; Taylor et al. 2011; Tavecchio et al. 2010) and a weak detection reported by Orr et al. (2011).

An additional difficulty for such constraints is that the spectrum of hard blazars might be composed of two contributions. Apart from the direct γ-ray emission from the primary source, an additional contribution is expected from the γ-ray cascade initiated in the intergalactic medium (IGM) by the absorbed VHE γ-rays (Aharonian et al. 1994; Plaga 1995). The overall flux and the spectral shape of the cascade contribution are determined by the strength of the extragalactic magnetic field (EGMF; Plaga 1995; Neronov & Semikoz 2007, 2009; Aharonian et al. 2002). Uncertainty of the EGMF strength introduces an uncertainty of the importance of the cascade contribution and prevents the measurement of the slope of the intrinsic γ-ray spectrum of the source. In fact, the limits on the EBL derived up to now are based on an underlying assumption about the EGMF strength (the EGMF should be strong enough to suppress the cascade contribution up to the ∼TeV energy band), which is not justified a priori.

If the assumption on the EGMF strength is relaxed, the γ-ray data can be used to measure the EGMF strength. The electron–positron pairs, created as a result of the absorption of multi-TeV photons, upscatter the cosmic microwave background as they cool, creating secondary emission in the GeV domain (Neronov & Semikoz 2009). With the mean free path of TeV γ-rays being $D_e ≳ 100(E_e/10$ TeV)$^{-1}$ Mpc, the production of these multi-TeV energy $e^−+e^+$ pairs occurs predominantly in extragalactic space. Furthermore, if non-negligible magnetic fields are present in the region these pairs are born into, they are significantly deflected from their initial directions, resulting in the secondary GeV photons having a reduced probability of reaching the observer. Thus, the apparent flux is suppressed at low energies. Observational evidence for the presence of such a suppression places constraints on the EGMF strength to be $>10^{-17}$ G (Neronov & Vovk 2010; Taylor et al. 2011; Tavecchio et al. 2010; Dolag et al. 2011; Dermer et al. 2011).

This limit on the EGMF is derived assuming a certain level of EBL density (a low EBL density derived by Franceschini et al. 2008 is used in most of the publications on the EGMF in order to derive conservative bounds). However, a variety of EBL models do exist (Gilmore et al. 2009; Kneiske et al. 2004; Stecker...
et al. 2006), which span the full range of the present uncertainty in the EBL density. This uncertainty therefore introduces an uncertainty into the bounds on the EGMF derived from the γ-ray data. Higher (lower) EBL density leads to stronger (weaker) absorption of the primary γ-ray flux along with a stronger (weaker) cascade contribution to the observed flux in the GeV range. The suppression of such stronger (weaker) cascade contribution would require a stronger (weaker) EGMF.

Thus, the limits on the EBL derived from the γ-ray data depend on the assumptions made about the EGMF strength and vice versa. This implies that the correct procedure for the derivation of limits on the EBL from the γ-ray data should include marginalization over the possible EGMF values. Conversely, the correct procedure for the derivation of the limits on the EGMF should include marginalization over the possible EBL densities and spectra.

Practical implementation of this correct procedure for the derivation of the EBL and EGMF bounds, however, presents a challenging task since the quality of the γ-ray data is usually insufficient for the exploration of the entire EBL–EGMF parameter space. Exploration of this parameter space requires the measurement of the source spectra both in the TeV and GeV energy ranges.

In this Letter, we report the observations of the blazar 1ES 0229+200 in the 1–300 GeV energy range using LAT’s data with three years of exposure. The detection of the source below 100 GeV provides the information necessary for the correct analysis of the EGMF-dependent upper bound on the EBL density and of the EBL-dependent lower bound on the EGMF strength. We present such bounds in the form of a two-dimensional exclusion plot in the “EBL density” versus “EGMF strength” parameter space.

2. ANALYSIS

In this work, we use publicly available data of the LAT instrument collected over the period from 2008 August until 2011 November. We use the Pass 7 data and analyze them using the Fermi Science Tools v9r23p1 software package, with the patches as of 2011 November 1st. We limit ourselves with the class 2 events, as is recommended by the Fermi/LAT team. We select only photons with energies in the 1–300 GeV range for the analysis. During the spectral fitting, we include in the analysis all the sources listed in the Fermi second year catalog (Abdo et al. 2011) within a 5° circle around the position of 1ES 0229+200.

The fluxes in separate energy bins are computed with the spectral indices of all sources frozen at the values quoted in the Fermi/LAT second year catalog; the spectral index of 1ES 0229+200 is fixed at the best-fit value in the 1–300 GeV band. For energies where 1ES 0229+200 is not detected in the bin, we compute the 90% confidence upper limit.

To compute the “spectral butterfly” we scan the value of the likelihood in the “index-normalization” parameter space and select the corresponding 68% confidence region.

We employ a Monte Carlo description of the electromagnetic cascades in order to determine the arriving spectra observed for the case of different strength of the EGMF (see Taylor et al. 2011 for more details). The shape of the EBL spectrum is assumed to follow that derived by Franceschini et al. (2008), while the normalization of the EBL is left free. A lower bound on the normalization of the EBL from the direct source counts (as summarized by Dominguez et al. 2011) is ≃15% lower than the normalization of the EBL model of Franceschini et al. (2008). Recent analysis of GeV to TeV spectra of several blazars (Orr et al. 2011), however, suggested that the EBL level is somewhat higher, reaching ≃60% of the EBL model of Franceschini et al. (2008) at the 2σ confidence level. Both these bounds are taken into account in our analysis.

In our calculations we consider the suppression of the cascade emission by time delay effects (Plaga 1995). The TeV γ-ray emission from the source is observed to be stable on the timescale of ≳3 yr, from the initial HESS observations of the source (Aharonian et al. 2007) until the recent re-observation by the Veritas telescope (Dermer et al. 2011). We do not consider the alternative possibility for the suppression of the cascade flux due to the extended nature of the cascade emission region.

The generalization of our analysis to this case, however, is straightforward, the main difference being that the suppression of the cascade emission due to the source extension would result in a somewhat higher bound on the EGMF strength (Taylor et al. 2011).

3. RESULTS

1ES 0229+200 is detected by LAT in the 1–300 GeV energy band with significance ≳7σ. The test statistics (TS) value found in the likelihood analysis is TS = 45. Modeling the source spectrum as a power law, we find the slope of the spectrum Γ = 1.36 ± 0.25 and normalization at 20 GeV (1.4 ± 0.5) × 10−15 (MeV cm2 s−1) (at the 68% confidence level). The spectrum of the source found from the LAT data is shown in Figure 1 together with the HESS spectrum at higher energies. The source is not detected below ≳3 GeV; only an upper limit on the source flux can be derived in this energy band.

As is discussed above, the source spectrum in the 3–300 GeV energy band can have two contributions: the direct γ-ray signal from the primary source and emission from the electromagnetic cascade developing in the IGM. It is not clear a priori if the measured spectral slope, consistent with Γ ≳ 1.5, characterizes the intrinsic source spectrum, the spectrum of the cascade component, or comprises a summed spectrum of the two (similar in strength) contributions. For instance, a spectral index harder then 1.5, as found in the analysis of Stecker & Sully (2008) in the TeV band, would be indicative of a GeV spectrum which results from the sum of both the intrinsic spectrum and that of the cascade. Different possibilities for the dominance of one of the two components in the spectrum are illustrated in the two panels of Figure 1. In both models, the normalization of the intrinsic spectrum is chosen to fit the HESS measurements in the TeV band. We also assume that the intrinsic source spectrum has a high-energy cutoff at Ecutoff = 5 TeV. As it was shown by Taylor et al. (2011), this choice minimizes the strength of the cascade contribution in the Fermi/LAT energy band.

In the upper panel the main contribution to the 3–300 GeV source flux is given by the direct flux of the primary source, shown by the thin solid line. This is possible only if the cascade component is suppressed by the influence of a strong enough EGMF. If the EGMF is negligible, the flux of the direct and cascade emission (thick solid line) will largely dominate over the direct emission. Strong EGMF (≥10−17 G) is needed to sufficiently suppress the cascade emission down to the level of the error bars of the LAT measurements in the 3–300 GeV range.

If the EGMF is weaker than ≳3 × 10−17 G, the cascade emission provides the dominant contribution to the source...
Figure 1. Top panel: the GeV–TeV spectral energy distribution (SED) under the assumption of a soft ($\Gamma = 1.5$) intrinsic source spectrum. Bottom panel: the GeV–TeV SED under the assumption of a hard ($\Gamma = 1.2$) intrinsic source spectrum. Lines for different values of EGMF strengths represent the sums of the intrinsic spectrum and the corresponding predicted cascade emission. In both cases the Fermi/LAT flux “butterfly” shown corresponds to the 68% confidence region.

The overall normalization of the cascade emission is determined by the density of the EBL. An increase of the EBL density leads to the stronger absorption of multi-TeV $\gamma$-rays and, consequently, to stronger cascade emission. On the contrary, reducing the EBL normalization down to the level of the lower bound from the direct source counts opens up the possibility of a weaker EGMF, down to $\sim 6 \times 10^{-18}$ G. The effect of changing the EBL normalization is illustrated in Figure 2. In this figure a spectral slope of $\Gamma = 1.5$ and EGMF of $10^{-16}$ G have been adopted, and three different (66%, 100%, and 150% in terms of the EBL level reported by Franceschini et al. 2008) levels of EBL have been used.
The maximal normalization of the EBL that can still be consistent with the data depends on the strength of the EGMF. Too strong an EBL can result in a large overprediction of the strength of the cascade emission, even after taking into account the suppression of this emission by the EGMF effects. Thus, the upper bound on the EBL derivable from the $\gamma$-ray observations of 1ES 0229+200 is EGMF dependent.

In order to find this bound, we compute the allowed ranges of the EBL normalization for a set of EGMF strengths and intrinsic spectrum spectral indices. The range of the EGMF strengths scanned over lay in the range $3 \times 10^{-19} \text{ G}$ to $10^{-14} \text{ G}$, while the spectral indices were varied within the range from 1.5 to 0. We then find the best-fit set of values in this “EGMF–EBL–$\Gamma$”parameter space, and chose an appropriate confidence region. The projection of this region onto the “EGMF–EBL” plane is shown in Figure 3 and comprises the part of the plot that is not hatched. The hatched part thus represents the EBL-dependent bound on the EGMF (or, equivalently, the EGMF-dependent bound on the EBL).

One can see from this figure that for EGMF strengths $B \sim 10^{-17} \text{ G}$ the upper bound sits at the level derived by Franceschini et al. (2008). If the EGMF is at the level...
of $\sim 10^{-15}$ G, the allowed EBL normalization is by a factor of two higher than that of the Franceschini et al. (2008) and Dominguez et al. (2011) models.

4. CONCLUSION

Following our investigations into the newly detected blazar 1ES 0229+200 with Fermi/LAT we find that, if the Franceschini et al. (2008) EBL level is adopted, an EGMF strength of at least $10^{-17}$ G is required in order for the inevitable GeV cascade spectral component to be consistent with observations. However, we find that, more generally, the EGMF lower bound is dependent on the EBL level adopted, as demonstrated in Figure 3.

One should keep in mind that this bound is derived for large ($\lambda_B > 1$ Mpc) correlation lengths of the EGMF, and scales approximately as $\lambda_B^{-1/2}$ for $\lambda_B / 1$ Mpc. Our result lies in agreement with previous findings (Taylor et al. 2011; Huan et al. 2011). Under the assumption that the source is stable on a timescale much longer than 3 years, a larger bound on the EGMF is obtained (Neronov & Vovk 2010; Taylor et al. 2011; Dolag et al. 2011; Tavecchio et al. 2010).

We also find that an intrinsic blazar spectral index of $\Gamma = 1.5$ is able to sit in agreement with observations of 1ES 0229+200 by Fermi/LAT ($\Gamma = 1.36 \pm 0.25$). Thus, our results can find agreement with the underlying assumptions behind previous EBL constraint calculations by Aharonian et al. (2006). However, the remaining uncertainty in the origin of the blazar’s spectral shape in the GeV domain leaves open the possibility for a harder intrinsic spectrum ($\Gamma < 1.5$).

We note that in previous works of Aharonian et al. (2006) and Orr et al. (2011) the authors made the implicit assumption for the absence of the cascade contribution in the GeV–TeV domain, which is equivalent to the presence of the strong EGMF with $B \gtrsim 10^{-15}$ G. As can be seen from Figure 3, for such a strong field our result is also compatible with the level of EBL found by Orr et al. (2011). For weaker fields, $B \sim 10^{-17}$ G, we are also compatible with the findings of Dominguez et al. (2011). However, for such weak fields a proper account should be given of the GeV–TeV cascade component contribution.

Future observations with ground-based Cerenkov telescopes, such as MAGIC Stereo, HESS 2, and CTA, will dramatically improve the measurements of blazar spectra below $\sim 100$ GeV, allowing much better constraints on the EGMF and EBL. In the particular case of 1ES 0229+200, if the intrinsic spectrum is hard, the presented EGMF lower bound may be transformed to a measurement, helping to better understand the nature of the EGMF.
