Optical properties of AFe2As2 (A=Ca, Sr, and Ba) single crystals

Abstract
The detailed optical properties have been determined for the iron-based materials AFe2As2, where A=Ca, Sr, and Ba, for light polarized in the iron-arsenic (a-b) planes over a wide frequency range, above and below the magnetic and structural transitions at TN=138, 195, and 172 K, respectively. The real and imaginary parts of the complex conductivity are fit simultaneously using two Drude terms in combination with a series of oscillators. Above TN, the free-carrier response consists of a weak, narrow Drude term, and a strong, broad Drude term, both of which show only a weak temperature dependence. Below TN there is a slight decrease of the plasma frequency but a dramatic drop in the scattering rate for the narrow Drude term, and for the broad Drude term there is a significant decrease in the plasma frequency, while the decrease in the scattering rate, albeit significant, is not as severe. The small values observed for the scattering rates for the narrow Drude term for T<<TN may be related to the Dirac conelike dispersion of the electronic bands. Below TN new features emerge in the optical conductivity that are associated with the reconstruction Fermi surface and the gapping of bands at Δ1=45–80 meV, and Δ2=110–210 meV. The reduction in the spectral weight associated with the free carriers is captured by the gap structure; specifically, the spectral weight from the narrow Drude term appears to be transferred into the low-energy gap feature, while the missing weight from the broad term shifts to the high-energy gap.

(Received 26 August 2016; revised manuscript received 30 September 2016; published 23 November 2016)

The detailed optical properties have been determined for the iron-based materials AFe$_2$As$_2$, where A = Ca, Sr, and Ba, for light polarized in the iron-arsenic (a-b) planes over a wide frequency range, above and below the magnetic and structural transitions at $T_N = 138$, 195, and 172 K, respectively. The real and imaginary parts of the complex conductivity are fit simultaneously using two Drude terms in combination with a series of oscillators. Above $T_N$, the free-carrier response consists of a weak, narrow Drude term, and a strong, broad Drude term, both of which show only a weak temperature dependence. Below $T_N$ there is a slight decrease of the plasma frequency but a dramatic drop in the scattering rate for the narrow Drude term, and for the broad Drude term there is a significant decrease in the plasma frequency, while the decrease in the scattering rate, albeit significant, is not as severe. The small values observed for the scattering rates for the narrow Drude term for $T \ll T_N$ may be related to the Dirac conelike dispersion of the electronic bands. Below $T_N$ new features emerge in the optical conductivity that are associated with the reconstruction Fermi surface and the gapping of bands at $\Delta_2 \simeq 45–80$ meV, and $\Delta_2 \simeq 110–210$ meV. The reduction in the spectral weight associated with the free carriers is captured by the gap structure: specifically, the spectral weight from the narrow Drude term appears to be transferred into the low-energy gap feature, while the missing weight from the broad term shifts to the high-energy gap.

I. INTRODUCTION

The discovery of the iron-based superconductors has resulted in an intensive investigation of this class of materials in the hope of discovering new compounds with high superconducting critical temperatures ($T_c$’s) [1–4]. The iron-arsenic materials are characterized by Fe-As sheets separated by layers of different elements or chemical structures. One material, BaFe$_2$As$_2$, is particularly useful as superconductivity can be induced by the application of pressure [5–8], as well as electron [9–12], hole [13–15], or isovalent doping [16–19], with $T_c$’s as high as 40 K in the hole-doped material. At room temperature, BaFe$_2$As$_2$ is a paramagnetic metal with a tetragonal structure. The resistivity in the planes decreases with temperature until it drops anomalously as the material undergoes a magnetic transition at $T_N \simeq 138$ K to a spin-density-wave (SDW) -like antiferromagnetic ground state that is also accompanied by a structural transition to an orthorhombic phase [20–22]. The resistivity also displays a slight anisotropy close to and below $T_N$, being slightly larger along the $b$ axis than along $a$ [23]; however, this anisotropy decreases dramatically if the samples are annealed [24]. The related materials CaFe$_2$As$_2$ and SrFe$_2$As$_2$ have similar transport properties due to magnetic and structural transitions that occur at $T_N \simeq 172$ and 195 K, respectively [25–30].

The broad interest in this family of materials has resulted in a number of optical studies [31–41]. Early investigations treated the free-carrier response using only a single band. However, a minimal description of the electronic structure of the iron-arsenic materials consists of hole and electron pockets at the center and corners of the Brillouin zone, respectively [42,43]. As a result, more recent studies consider a two band approach (the so-called two-Drude model) in which the electron and hole pockets are treated as separate electronic subsystems [44]. Above $T_N$, this model reveals the presence of a narrow Drude response that has a strong temperature dependence in combination with a broad Drude term that is essentially temperature independent. Below $T_N$, the optical conductivity undergoes dramatic changes due to the reconstruction of the Fermi surface [45–51]; however, one of the most detailed optical studies on this family of materials restricts the two-Drude analysis to $T \gtrsim T_N$ [39].

In this study the detailed temperature dependence of the complex optical properties in the $a-b$ planes of single crystals of BaFe$_2$As$_2$, SrFe$_2$As$_2$, and CaFe$_2$As$_2$, have been determined above and below $T_N$. This allows the evolution of the electronic properties and the SDW gaplike features ($T < T_N$) with the different alkaline-earth-metal atoms to be tracked. The complex conductivity has been modeled using the two-Drude model. Above $T_N$, the complex conductivity is described by a strong, broad Drude response, and a narrow, less intense term, both of which exhibit only a weak temperature dependence, in combination with a strong interband feature at about 0.5 eV; these results are in good agreement with other works. Below $T_N$, there is a dramatic narrowing of the Drude responses and a suppression of the low-frequency conductivity as spectral weight is transferred to two new gaplike features that appear below about 200 meV. To avoid the difficulties of false convergence typically associated with the extra degrees of freedom due to these new gap features, we introduce the constraint that the spectral weight due to the Drude terms above $T_N$ must be captured by the Drude terms and the two oscillators used to describe the gap features below $T_N$. Using this approach, reliable convergence is achieved and we are able to track the detailed temperature dependence of the Drude and Lorentz parameters below $T_N$.

We observe the same response in all three materials; namely, just below \( T_N \) there is a slight reduction of the plasma frequency for the narrow term, but a dramatic decrease of the scattering rate, while for the broad Drude term there is a significant reduction of both the plasma frequency and the scattering rate. The missing spectral weight in the narrow term is attributed to a slight reduction of the plasma frequency, while for the broad Drude term there is a more significant reduction of the plasma frequency as well as a dramatic decrease of the missing spectral weight in the narrow term, but a dramatic decrease of the bandwidth of the broad term. The temperature dependence of the (d) plasma frequencies and (e) scattering rates for the broad and narrow Drude components above and below \( T_N \).

We observe the same response in all three materials; namely, just below \( T_N \) there is a slight reduction of the plasma frequency for the narrow term, but a dramatic decrease of the scattering rate, while for the broad Drude term there is a significant reduction of both the plasma frequency and the scattering rate. The missing spectral weight in the narrow term is attributed to a slight reduction of the plasma frequency, while for the broad Drude term there is a more significant reduction of the plasma frequency as well as a dramatic decrease of the missing spectral weight in the narrow term, but a dramatic decrease of the bandwidth of the broad term. \[ \sigma(\omega) = \sigma(\infty) + \sigma(0) \]
region with a commensurate transfer of spectral weight to the peaks that emerge at \(\approx 360\) and 900 cm\(^{-1}\). The spectral weight is defined as the area under the conductivity curve over a given interval,

\[
S(\omega) = \int_0^\omega \sigma(\omega')d\omega'.
\]

These results are in good agreement with other optical studies of this material [31–40].

The real and imaginary parts of the complex optical conductivity have been fit simultaneously with the Drude-Lorentz model using a nonlinear least-squares technique. For \(T > T_N\), the data was initially fit using a single Drude component and a series of Lorentzian oscillators to reproduce the interband transitions; however, even with extremely over-damped oscillators, the returned fits were of poor quality. A low-frequency Lorentz oscillator was introduced to improve the quality of the fit; however, the best result was obtained when the frequency of this oscillator went to zero and a second Drude component was recovered. Given the multiband nature of this material, this is a natural result. While there are as many as five Fermi surfaces, we have adopted a minimal description that only considers two sets of carriers; this approach has the advantage of producing good fits, as well as keeping the total number of parameters (degrees of freedom) relatively low, an approach that typically results in fits with good convergence.

The fit to the real part of the optical conductivity using the two-Drude model above \(T_N\) at 200 K is shown in Fig. 1(b) where the individual Drude and Lorentz contributions are shown. The data is reproduced quite well by a narrow and a broad Drude term, with \(\omega_{p,D,1} \approx 4200\) cm\(^{-1}\) and \(1/\tau_{D,1} \approx 90\) cm\(^{-1}\), and \(\omega_{p,D,2} \approx 12200\) cm\(^{-1}\) and \(1/\tau_{D,2} \approx 1100\) cm\(^{-1}\), respectively, as well as bound excitations at \(\omega_1 \approx 4450\) cm\(^{-1}\) and \(\omega_2 \approx 13800\) cm\(^{-1}\), which are attributed to interband transitions [58,59]; the parameters for the Drude components, as well as the first two Lorentzian oscillators, are listed in Table I(a). The observation of narrow and broad terms in the two-Drude analysis is in agreement with other optical studies [37–40], and appears to be a general result for most of the iron-based materials that incorporate iron-arsenic sheets. If the plasma frequencies for the free carriers are added in quadrature [Eq. (3)], then the derived plasma frequency \(\omega_p \approx 12900\) cm\(^{-1}\) is in good agreement with a previous study on this material that considered only a single Drude component [31].

This approach has also been applied to the optical conductivity below \(T_N\), where two new oscillators at \(\omega_{01} \approx 360\) cm\(^{-1}\) and \(\omega_{02} \approx 900\) cm\(^{-1}\) have been included to reproduce the broad peaks that emerge in the optical conductivity at low temperature. However, the six extra degrees of freedom introduced by the two new oscillators can lead to a false convergence with nonunique solutions. By observing that the loss of spectral weight of the free carriers below \(T_N\) appears to be captured by the two new oscillators, we can introduce the constraint that the redistribution of the spectral weight among these fitted parameters must be a conserved quantity. This is equivalent to the statement that below \(\approx 5000\) cm\(^{-1}\) the spectral weight is roughly constant. Thus, above and below \(T_N\),

\[
\omega_p \approx \begin{cases} 
\frac{\sqrt{\omega_{p,D,1}^2 + \omega_{p,D,2}^2}}{\Omega_0} & (T > T_N) \\
\frac{\sqrt{\omega_{p,D,1}^2 + \omega_{p,D,2}^2 + \Omega_{01}^2 + \Omega_{02}^2}}{\Omega_0} & (T < T_N).
\end{cases}
\]

where \(\Omega_{01}\) and \(\Omega_{02}\) are the strengths of the two new oscillators; this constraint leads unique solutions (this is explored in more detail in the Supplemental Material). The results of the fit to the data at 100 K using this approach are shown in Fig. 1(c); the Drude components have narrowed and lost spectral weight, which has shifted to the two new oscillators; the excitation \(\omega_1\) has shifted upwards slightly to \(\approx 4600\) cm\(^{-1}\), but otherwise shows relatively little temperature dependence below \(T_N\) [Table I(a)]. These results are in good agreement with the optical conductivity of a detwinned sample at 5 K [37], which show that the broad Drude component is only observed along the \(a\) axis, while the narrow Drude component is observed in both the \(a\) and the \(b\) directions. The fact that the narrow Drude component is isotropic suggests that it is not related to the magnetic order in this material.

The temperature dependence of the plasma frequencies and scattering rates for the two Drude components are shown in Figs. 1(d) and 1(e), respectively; above \(T_N\) the parameters are essentially temperature independent, which is not surprising given the weak temperature dependence of the optical conductivity. Below \(T_N\), the plasma frequency for the broad Drude component decreases dramatically from \(\omega_{p,D,2} \approx 12300 \rightarrow 3800\) cm\(^{-1}\), while the plasma frequency for the narrow component decreases only slightly, \(\omega_{p,D,1} \approx 4200 \rightarrow 3400\) cm\(^{-1}\). The total carrier concentration is observed to decrease from \(\omega_{p,D} \approx 12900 \rightarrow 5100\) cm\(^{-1}\). This roughly 85% decrease in the number of free carriers is in agreement with previous estimates [31,32]. The values for the plasma frequencies of the narrow and broad Drude components, and the intensities of the two new oscillators obey the constraint in Eq. (3), with \(\omega_2 \approx 13200 \pm 500\) cm\(^{-1}\) (\(T \ll T_N\)). A closer examination of the values returned from the fits reveals that the missing spectral weight from the narrow Drude component appears to be captured by \(\omega_{01}\),

\[
\omega_{p,D,1}^2(T \geq T_N) \approx \omega_{p,D,1}^2(T \ll T_N) + \Omega_{01}^2,
\]

and likewise the loss of spectral weight from the broad Drude component appears to be captured by \(\omega_{02}\),

\[
\omega_{p,D,2}^2(T \geq T_N) \approx \omega_{p,D,2}^2(T \ll T_N) + \Omega_{02}^2.
\]

Allowing that the Fermi surface reconstruction below \(T_N\) results in the partial gapping of the two pockets, it is reasonable to associate \(\omega_{01}\) and \(\omega_{02}\) with gaplike features in the optical conductivity that appear to be more or less isotropic in the \(a\)-\(b\) planes [37,60]. The average optical gap for the narrow Drude band is therefore estimated to be \(\Delta_1 \approx 44\) meV, while for the broad Drude band it is \(\Delta_2 \approx 112\) meV. These estimates are in good agreement with the peaks observed in the Raman response [61] and the optical conductivity [31,39], as well as the values for \(\Delta_1\) and \(\Delta_2\) determined from them (in this work the average value for the gap is always associated with the peak in the conductivity).
Table I. The results of the nonlinear least-squares fit of the two-Drude model with Lorentz oscillators to the complex conductivity of BaFe$_2$As$_2$, SrFe$_2$As$_2$, and CaFe$_2$As$_2$ at all measured temperatures. The terms $D_1$ and $D_2$ denote the two Drude contributions, while $L_1$ and $L_2$ are the two low-frequency Lorentzian oscillators; the two new oscillators that appear below $T_N$ are denoted $L_{01}$ and $L_{02}$. The oscillators above 0.5 eV display relatively little temperature dependence. The estimated errors for the location and width are typically 2% or less, and 5% or less for the plasma frequency (oscillator strength). All units are in cm$^{-1}$ unless otherwise indicated. A convenient conversion is 1 eV = 8065.5 cm$^{-1}$.

allowing values of $1/\tau_D$, the response of the narrow Drude component now extends to much higher frequencies, allowing a precise determination of the scattering rate.

The scattering rate for the broad Drude term drops abruptly below $T_N$, $1/\tau_{D,2} \approx 1200 \rightarrow 190$ cm$^{-1}$, while the scattering rate for the narrow Drude component drops by over an order of magnitude, $1/\tau_{D,1} \approx 90 \rightarrow 3$ cm$^{-1}$. As Fig. 1(c) demonstrates, it is rather difficult to determine small values of $1/\tau_D$ from fits to only the real part of the Drude optical conductivity,

$$
\sigma_{1,D}(\omega) = \frac{\sigma_0}{1 + \omega^2\tau_D^2},
$$

which has the form of a Lorentzian centered at zero frequency with a full width at half maximum of $1/\tau_D$ and $\sigma_0 = 2\pi\omega_{p,D}\tau_D/Z_0$. This difficulty is further illustrated in the fit to the data at 5 K in Fig. 2(a), where most of the spectral weight of the narrow Drude component lies below 100 cm$^{-1}$; if the fit was restricted to only $\sigma_1(\omega)$, the narrow scattering rate would be nearly impossible to determine with any degree of confidence. However, in our analysis the real and imaginary parts of the optical conductivity are fit simultaneously. The imaginary part of the Drude conductivity,

$$
\sigma_{2,D}(\omega) = \frac{\sigma_0\omega\tau_D}{1 + \omega^2\tau_D^2},
$$

is considerably broader than the real part, as Fig. 2(b) indicates, allowing values of $1/\tau_D \lesssim 10$ cm$^{-1}$ to be fit reliably. Thus, despite the loss of free carriers below $T_N$, the decrease in the scattering rate for the narrow Drude component is responsible for the increasingly metallic behavior at low temperature [31].

**B. SrFe$_2$As$_2$**

The temperature dependence of the real part of the optical conductivity for SrFe$_2$As$_2$ ($T_N \approx 195$ K) for light polarized in the $a$-$b$ planes is shown in Fig. 3(a) in the infrared region. The overall temperature dependence is quite similar to that of BaFe$_2$As$_2$. Above $T_N$, the conductivity is metallic and displays little temperature dependence, while below $T_N$ the dramatic narrowing of free-carrier contribution and the decrease in the low-frequency conductivity leads to the redistribution of spectral weight over a much larger energy scale with a prominent peak appearing at $\approx 1400$ cm$^{-1}$ (the reflectance and the optical conductivity are shown over a broader energy range in Figs. S4 and S5 in the Supplemental Material); however, this feature was observed at a much lower energy, $\approx 900$ cm$^{-1}$, in BaFe$_2$As$_2$.

The optical conductivity has been fit using the two-Drude model. The result for the fit just above $T_N$ at 200 K is shown in Fig. 3(b) where it is decomposed into the individual contributions from the Drude and Lorentz components. The free-carrier response is reproduced using a narrow and a broad Drude component, with $\omega_{p,D,1} \approx 5100$ cm$^{-1}$ and $1/\tau_{D,1} \approx 300$ cm$^{-1}$, and $\omega_{p,D,2} \approx 17700$ cm$^{-1}$ and $1/\tau_{D,2} \approx 2360$ cm$^{-1}$, respectively, and a series of oscillators at $\omega_1 \approx 5000$ cm$^{-1}$ and $\omega_2 \approx 11200$ cm$^{-1}$ [Table I(b)]. The plasma frequencies for the Drude components are both larger than what was observed in BaFe$_2$As$_2$, with the combined value for $\omega_p \approx 18400 \pm 600$ cm$^{-1}$. These results are consistent with other optical studies of this material [31,39].

The fits to the complex conductivity for $T < T_N$ are again performed using the constraint in Eq. (3). The results of the fit at 100 K, shown for the real part of the optical conductivity in Fig. 3(c), indicate that both Drude components decrease in strength and narrow below $T_N$ at the same time that spectral weight is transferred into two new Lorentz oscillators at $\omega_{01} \approx 470$ cm$^{-1}$ and $\omega_{02} \approx 1450$ cm$^{-1}$ [Table I(b)]. The detailed temperature dependence of the plasma frequencies and scattering rates are shown in Figs. 3(d) and 3(e), respectively. As previously noted, for $T > T_N$, the plasma frequencies display little or no temperature dependence; however, for $T < T_N$, $\omega_{p,D,1} \approx 5100 \rightarrow 3600$ cm$^{-1}$ for the narrow Drude component, while a much larger decrease, $\omega_{p,D,2} \approx 17700 \rightarrow 5000$ cm$^{-1}$, is observed for the broad Drude component. The scattering rate for the narrow Drude component decreases significantly, $1/\tau_{D,1} \approx 300$ cm$^{-1}$ just above $T_N$ to $\approx 13$ cm$^{-1}$ at low temperature. The decrease in the scattering rate for the broad Drude component, $1/\tau_{D,2} \approx 2350 \rightarrow 330$ cm$^{-1}$, while significant, is less dramatic. The total carrier concentration is observed to decrease from $\omega_p \approx 18400 \rightarrow 6200$ cm$^{-1}$; this $\approx 89\%$ decrease in the number of free carriers for $T < T_N$ is somewhat larger than what was observed in BaFe$_2$As$_2$ [31]. The values for the plasma frequencies of the narrow and broad Drude components, and the intensities of the two new oscillators sum to $\omega_p \approx 17320 \pm 600$ cm$^{-1}$ ($T < T_N$), indicating that the spectral weight from the narrow and broad Drude components has been almost entirely

transferred into the two new oscillators, $\omega_{01}$ and $\omega_{02}$. The estimates for the optical gap energies are $\Delta_1 \simeq 58$ meV and $\Delta_2 \simeq 180$ meV, respectively. The value for the large gap is in good agreement with Raman results [62]; however, both of these values are somewhat larger than previous optical estimates [39]. A possible source of uncertainty is that the gap features in this material are much broader than in BaFe$_2$As$_2$, making them more difficult to fit unless controls such as the conservation of spectral weight described in Eq. (3) are introduced.

C. CaFe$_2$As$_2$

The temperature dependence of the real part of the optical conductivity for CaFe$_2$As$_2$ ($T_N \simeq 172$ K) with light polarized in the $a$-$b$ planes is shown in Fig. 4(a) in the infrared region. Unlike the previous two materials, the conductivity displays a relatively large temperature dependence above $T_N$ (the reflectance and the optical conductivity are shown over a broader energy range in Figs. S6 and S7 in the Supplemental Material); this is entirely due to the strong temperature dependence of the narrow Drude component and $1/\tau_{D1}$ [Table I(c)]. Below $T_N$, there is once again the characteristic narrowing of the free-carrier response coupled with the dramatic suppression of the low-frequency conductivity and the transfer of spectral weight into the peak that emerges at $\simeq 1720$ cm$^{-1}$.

The result of the fit to the complex conductivity above $T_N$ at 200 K using the two-Drude model is compared to the real part in Fig. 4(b), where it is decomposed into its individual contributions. As in previous cases, the free-carrier

195142-6
response is described quite well by a narrow and a broad Drude component of \( \omega_p, D_1 \sim 8900 \text{ cm}^{-1} \) and \( 1/\tau_D, D_1 \sim 490 \text{ cm}^{-1} \), and \( \omega_p, D_2 \sim 19300 \text{ cm}^{-1} \) and \( 1/\tau_D, D_2 \sim 3100 \text{ cm}^{-1} \), and a series of oscillators at \( \omega_0, 1 \sim 5700 \text{ cm}^{-1} \) and \( \omega_0, 2 \sim 12 \times 8000 \text{ cm}^{-1} \) [Table I(a)]. The resulting value of \( \omega_p \sim 21 \pm 1200 \text{ cm}^{-1} \) is larger than was observed in either of the other two materials, in agreement with a previous work [39]. Above \( T_N \), the scattering rate for the broad Drude component has a weak temperature dependence, while the narrow component has a strong temperature dependence, decreasing from \( 1/\tau_D, 1 \sim 730 \text{ cm}^{-1} \) at room temperature to \( \sim 400 \text{ cm}^{-1} \) just above \( T_N \) [Table I(c)].

Below \( T_N \) the two-Drude model is fit to the complex conductivity using the previously described technique. The results of the fit at 100 K, shown for the real part of the optical conductivity in Fig. 4(c), once again show that both Drude components decrease in strength and narrow at the same time that spectral weight is transferred into two new Lorentz oscillators at \( \omega_0, 1 \sim 660 \text{ cm}^{-1} \) and \( \omega_0, 2 \sim 1670 \text{ cm}^{-1} \) [Table I(c)]. The detailed temperature dependence of the plasma frequencies and scattering rates are shown in Figs. 4(d) and 4(e), respectively. While the plasma frequencies display little or no temperature dependence for \( T > T_N \), below \( T_N \) the narrow Drude component decreases somewhat, \( \omega_p, D_1 \sim 8520 \rightarrow 4400 \text{ cm}^{-1} \), while a more dramatic decrease, \( \omega_p, D_2 \sim 18640 \rightarrow 5500 \text{ cm}^{-1} \), is observed for the broad Drude component. The scattering rate for the narrow Drude component decreases dramatically, \( 1/\tau_D, 1 \sim 400 \text{ cm}^{-1} \) just above \( T_N \) to \( \sim 11 \text{ cm}^{-1} \) at low temperature; the decrease in the scattering rate for the broad Drude component, \( 1/\tau_D, D_2 \sim 2700 \rightarrow 520 \text{ cm}^{-1} \), while not as dramatic, is still significant. The total carrier concentration is observed to decrease from \( \omega_p, D \sim 21 \times 200 \rightarrow 7040 \text{ cm}^{-1} \); this \( \sim 89% \) decrease in the total number of free carriers for \( T \ll T_N \) is similar to what was observed in SrFe\(_2\)As\(_2\).

The values for the plasma frequencies of the narrow and broad Drude components, and the intensities of the two new oscillators sum to \( \omega_p \sim 16540 \text{ cm}^{-1} \) (\( T \ll T_N \)), indicating that a significant portion of the spectral weight has been shifted into the two new oscillators, \( \omega_0, 1 \) and \( \omega_0, 2 \), leading to estimates for the optical gap energies of \( \gtrsim 82 \) and \( \gtrsim 207 \text{ meV} \), respectively. Both of these values are somewhat larger than previous optical estimates [39], and the value for the large gap is larger than the strong feature observed in the Raman response [63]. However, as in the case of SrFe\(_2\)As\(_2\), the gap features are rather broad, and in the absence of controls, are difficult to fit reliably.

### D. Common features

Common to all these materials is the result that above \( T_N \) the optical conductivity is reproduced by a strong, broad Drude response that shows little temperature dependence, and a weaker, narrower Drude response where the scattering rate displays a slight temperature dependence. For the progression SrFe\(_2\)As\(_2\), for \( A = \text{Ba, Sr, and Ca} \), the plasma frequencies for both the narrow and broad Drude components, the scattering rates, and the gaplike features are all increasing (although we would remark that \( 1/\tau_D, 1 \) and \( 1/\tau_D, 2 \) are substantially lower in BaFe\(_2\)As\(_2\) than in either of the other two materials). The trends in the electronic properties appear to follow the electronegativity (electron affinity) of the alkaline-earth-metal atoms (Table II). The Pauling electronegativities of Ba, Sr, and Ca are \( \chi_P = 0.89, 0.95 \) and 1.00, respectively. The increasing electron affinity also leads to a decrease in the covalent radius of 1.98, 1.92, and 1.74 Å, which is also connected to the decreasing c-axis lattice parameter of 13, 12.4, and 11.7 Å for the Ba [20], Sr [25], and Ca [64] materials, respectively. Thus, while the electronegativities of the alkaline-earth-metal atoms are a useful guide for establishing trends in these materials, we would caution that the electronic structure, especially below \( T_N \), is quite complicated, and that detailed structural properties should also be taken into consideration.

In each material, below \( T_N \), despite the appearance of a new structure in the optical conductivity that signals the reconstruction and partial gapping of the Fermi surface, the two-Drude model continues to reproduce the free-carrier response quite well. For the broad Drude component, both the plasma frequency and the scattering rate undergo a significant reduction below \( T_N \), while for the narrow Drude component the plasma frequency decreases only slightly, while the scattering rate decreases by over an order of magnitude. More specifically, \( 1/\tau_D, 1 \) has a strong temperature dependence below \( T_N \), while \( 1/\tau_D, 2 \) undergoes an abrupt drop just below \( T_N \), below which it remains relatively constant (Table I). The dramatic collapse of the scattering rate for the narrow Drude component for \( T \ll T_N \) is reminiscent of what is observed in other materials where a Fermi surface reconstruction leads to large portions of the Fermi surface being removed, with a concomitant loss of free carriers; in some special cases this is referred to as a “nodal metal” [65–67], but more generally it describes any semimetal with a very small Fermi surface. In multiband materials, it is not uncommon for one (or more) of the scattering rates to be quite small, typically on the order of several cm\(^{-1} \) [68,69]. The very small values of \( 1/\tau_D, 1 \) at low temperatures is similar to what is seen in some Weyl and
Dirac semimetals, where scattering rates are only a few cm$^{-1}$ [70–72]; indeed, the observation [47] and calculation [60] of Dirac conelike dispersion of the electronic bands of BaFe$_2$As$_2$ below $T_N$ suggests that this is a natural comparison.

In all three materials, a structure is observed in the optical conductivity that is associated with the partial gapping of the Fermi surface that appears below $T_N$, a small gap ($\Delta_1$) and a large gap ($\Delta_2$); these features may be associated transitions between relatively flat bands located at high-symmetry points ($\Gamma$ and $M'$) [60]. The values range from $\Delta_1 \simeq 44–82$ meV for the small gap to $\Delta_2 \simeq 112–207$ meV for the large gap. This yields values of $\Delta_1/k_B T_N \simeq 3.8–5.5$ and $\Delta_2/k_B T_N \simeq 9.4–14$, where $k_B$ is Boltzmann’s constant. As previously noted, both $\Delta_1$ and $\Delta_2$ are increasing across this family of materials; however, the ratio of the gaps shows little variation, with $\Delta_2/\Delta_1 \simeq 2.5–3$, suggesting that the gaps scale with the electronic bandwidth.

**IV. CONCLUSIONS**

The temperature dependence of the detailed optical properties of BaFe$_2$As$_2$, SrFe$_2$As$_2$, and CaFe$_2$As$_2$ single crystals have been determined over a wide energy range above and below $T_N \simeq 138, 195$, and 172 K, respectively, for light polarized in the $a$-$b$ planes. The complex optical properties may be reliably fit using two Drude components in combination with a series of Lorentz oscillators. Above $T_N$ in all three materials, the free-carrier response consists of a weak, narrow Drude term, and a much stronger, broader Drude term, both of which display only a weak temperature dependence. The plasma frequencies of both the narrow and broad terms are observed to increase in the Ba, Sr, and Ca family of materials. Below $T_N$ the Fermi surface reconstruction produces dramatic changes in the complex conductivity. While the materials are increasingly metallic at low temperature, there is a decrease in the low-frequency spectral weight from both the narrow and broad Drude components and a commensurate transfer to the gaplike features ($\Delta_1$ and $\Delta_2$) observed at higher energies. The complex conductivity may only be reliably fit using the two-Drude model if the constraint that the spectral weight is constant below roughly 5000 cm$^{-1}$ is introduced. The loss of spectral weight from the narrow Drude component is apparently transferred to peak in the optical conductivity associated with the low-energy gap $\Delta_1$, while the loss of spectral weight from the broad Drude component is apparently transferred to the high-energy gap $\Delta_2$.

Below $T_N$, both the plasma frequency and the scattering rate in the broad Drude term decrease substantially; the plasma frequency in the narrow Drude term experiences a slight decrease, but the scattering rate decreases by over an order of magnitude, and in the case of BaFe$_2$As$_2$, is only a few cm$^{-1}$ for $T \ll T_N$. Dirac semimetals often display extremely small scattering rates, suggesting that the extraordinarily low value for the scattering rate in these materials may be related to the Dirac conelike dispersion observed in the electronic bands below $T_N$.

**ACKNOWLEDGMENTS**

We would like to acknowledge useful discussions with E. Bascones and Y. Gallais. A.A. acknowledges funding from the Ambizione grant of the Swiss National Science Foundation. Work at the Ames Laboratory (S.L.B. and P.C.C.) was supported by the U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division. The Ames Laboratory is operated for the U.S. Department of Energy by Iowa State University under Contract No. DE-AC02-07CH11358. We would like to thank Alex Thaler and Sheng Ran for help in samples’ synthesis. Work at Brookhaven National Laboratory was supported by the Office of Science, U.S. Department of Energy under Contract No. DE-SC0012704.
