Abstract. The distance-redshift relation plays a fundamental role in constraining cosmological models. In this paper, we show that measurements of positions and time delays of strongly lensed images of a background galaxy, as well as those of the velocity dispersion and mass profile of a lens galaxy, can be combined to extract the angular diameter distance of the lens galaxy. Physically, as the velocity dispersion and the time delay give a gravitational potential \((GM/r)\) and a mass \((GM)\) of the lens, respectively, dividing them gives a physical size \((r)\) of the lens. Comparing the physical size with the image positions of a lensed galaxy gives the angular diameter distance to the lens. A mismatch between the exact locations at which these measurements are made can be corrected by measuring a local slope of the mass profile. We expand on the original idea put forward by Paraficz and Hjorth, who analyzed singular isothermal lenses, by allowing for an arbitrary slope of a power-law spherical mass density profile, an external convergence, and an anisotropic velocity dispersion. We find that the effect of external convergence cancels out when dividing the time delays and velocity dispersion measurements. We derive a formula for the uncertainty in the angular diameter distance in terms of the uncertainties in the observables. As an application, we use two existing strong lens systems, B1608+656 \((z_L = 0.6304)\) and RXJ1131–1231 \((z_L = 0.295)\), to show that the uncertainty in the inferred angular diameter distances is dominated by that in the velocity dispersion, \(\sigma^2\), and its anisotropy. We find that the current data on these systems should yield about 16% uncertainty in \(D_A\) per object. This improves to 13% when we measure \(\sigma^2\) at the so-called sweet-spot radius. Achieving 7% is possible if we can determine \(\sigma^2\) with 5% precision.

Keywords: gravitational lensing, galaxy dynamics

1 Introduction

Individual strong gravitational lens systems can be used to measure cosmological parameters via a combination of the cosmological distances [1–5]. Recently, a particular combination of the distances called the “time-delay distance” of strongly lensed time delay systems has yielded precise determinations of the Hubble constant [6–8]. The time-delay distance is the angular diameter distance to the lens from Earth, $D_A(EL)$, multiplied by the distance to the source, $D_A(ES)$, divided by the distance between the lens and the source, $D_A(LS)$. While this combination is sensitive to the Hubble constant, it is less so to the other cosmological parameters than $D_A(EL)$ itself [9]. See figure 1 for the definition of these distances.

To extract more cosmological information acquirable from the strong lens time delay systems, Paraficz and Hjorth [10] have shown that, by assuming the density profile of the lens galaxy, one can obtain $D_A(EL)$ from time-delay lenses. The basic physics behind this idea is simple: the velocity dispersion gives the depth of the potential at the point where it is measured, and the time delay gives the mass of the lens galaxy enclosed within the position at which images are formed. Thus, dividing them gives the physical size of the system. We
can then estimate $D_A(EL)$ by dividing the physical size by the angular separation of lensed image positions. Their analysis was limited to the singular isothermal sphere (SIS) density profile, as well as to an isotropic velocity dispersion. In this paper, we show that this simple physical picture holds even when we extend the analysis by including an arbitrary power-law profile, the effect of external convergence, and an anisotropic velocity structure. We show explicitly how to extract $D_A(EL)$ from the observational data, and provide an estimate of its associated uncertainty.

The rest of the paper is organized as follows. In section 2, we present the basic idea using a simplified SIS model, following ref. [10]. In section 3, we expand on ref. [10] by allowing for an arbitrary slope of a power-law spherical mass density profile and external convergence. In section 4, we derive an analytical formula relating the uncertainty in $D_A(EL)$ to the uncertainties in the observable quantities, and apply the formula to the observed strong lens time delay systems, B1608+656 and RXJ1131−1231. In section 5, we use Monte-Carlo simulations to study the effect of anisotropic velocity dispersion on the uncertainty in $D_A(EL)$. We conclude in section 6. In the appendix, we show how General Relativity allows us to calculate the deflection angle at the lens plane.

2 Basics of the analysis

2.1 The idea: a simple analysis using singular isothermal spheres

We review the basic idea with the simplest case in which the mass density profile of a lens galaxy is given by an SIS. This case has been worked out by Paraficz and Hjorth in 2009 [10]. The density distribution of an SIS lens, $\rho_{\text{SIS}}$, is given by

$$
\rho_{\text{SIS}}(r) = \frac{\sigma^2}{2\pi Gr^2},
$$

\[2.1\]
where $\sigma^2$ is the three-dimensional isotropic velocity dispersion. The Einstein ring radius, $\theta_E$, is related to $\sigma^2$ via

$$\sigma^2 = \theta_E^2 \frac{c^2}{4\pi} \frac{D_A(ES)}{D_A(LS)}.$$  \hfill (2.2)

Clearly, the relation between the two observable quantities, $\theta_E$ and $\sigma$, depends on the distance ratio.

To extract the actual angular diameter distance to the lens, $D_A(EL)$, instead of the ratio, we need to include the lensing time delay [11]. The presence of intervening mass between the observer and the source, usually galaxies and/or clusters of galaxies, causes two different components on time delay: the geometrical time delay and the potential time delay. Strongly lensed systems show multiple images as photons coming from the source take different paths: images are located at the closest approach to the lens of each path. The geometrical part of the time delay is caused by the fact that the total path lengths differ, while the potential part is caused by the difference in the depths of potential at each image position of the path.

In a SIS lens, the time delay between two images can be written as

$$\Delta t_{i,j} \equiv t_i - t_j = \frac{1 + z_L}{2c} \frac{D_A(EL)D_A(ES)}{D_A(LS)} (\theta_j^2 - \theta_i^2),$$ \hfill (2.3)

where $\theta_i$ is the angular separation between the $i$-th image and the center of the lens galaxy, and $t_i$ is the absolute time delay of the $i$-th image, i.e., the delay in comparison to the case where the lens is absent [12]. The distance ratio that appears in this relation is the time-delay distance, $D_{\Delta t} \equiv (1 + z_L)D_A(EL)D_A(ES)/D_A(LS)$, which depends primarily on $H_0$ and has a limited sensitivity to the other cosmological parameters, such as the equation of state of dark energy.

Remarkably, when we combine the above equation with equation (2.2) and $\theta_E = (\theta_i + \theta_j)/2$, we obtain the angular diameter distance to the lens:

$$D_A(EL) (\theta_j - \theta_i) = \frac{c^3}{4\pi\sigma^2} \frac{\Delta t_{i,j}}{1 + z_L}.$$ \hfill (2.4)

The physical interpretation of the above analysis is as follows: the velocity dispersion is determined by the gravitational potential of the lens, $GM/r$. The time delay gives the mass of the lens system, $GM$, and thus dividing them gives the physical size of the system, $r$. Since the angular scale of the system is directly observable via $\theta_j - \theta_i$, one can estimate the angular diameter distance to the lens. Equation (2.4) indeed gives the angular diameter distance as $D_A(EL) \propto \Delta t_{i,j}/[\sigma^2(\theta_j - \theta_i)]$; thus, the uncertainty in $D_A(EL)$ is given by the quadrature sum of the uncertainties in the time delay, velocity dispersion, and image position measurements.

As the velocity dispersion uncertainty is usually the biggest of all uncertainties, the uncertainty in $D_A(EL)$ is expected to be dominated by the velocity dispersion uncertainty. The goal of this paper is to extend this analysis to more general lenses.

### 2.2 Lensing theory and equations

Before we proceed, let us review some of general equations for strong lensing, following ref. [7]. Let the angular position of the image be $\hat{\theta}$ and that of the source be $\hat{\beta}$, as shown in figure 1.
The absolute time delay can be written as

\[
t(\vec{\theta}, \vec{\beta}) = \frac{1}{c}(1 + z_L) \frac{D_A(EL)D_A(ES)}{D_A(ES)} \frac{D_A(EL)}{D_A(LS)} \phi(\vec{\theta}, \vec{\beta}) ,
\]

(2.5)

where \( \phi \) is the so-called Fermat potential, which is defined as

\[
\phi(\vec{\theta}, \vec{\beta}) = \frac{(\vec{\theta} - \vec{\beta})^2}{2} - \psi(\vec{\theta}) .
\]

(2.6)

The first and the second terms in equation (2.5) are geometrical and potential time-delay terms, respectively. Here, \( \psi \) is the lens potential, which is calculated as

\[
\psi(\vec{\theta}) = \frac{1}{\pi} \int d^2 \theta' \kappa(\vec{\theta}') \ln |\vec{\theta} - \vec{\theta}'| ,
\]

(2.7)

where the lensing convergence field, \( \kappa \), is defined by

\[
\kappa(\vec{\theta}) \equiv \frac{\Sigma(\vec{\theta})}{\Sigma_{cr}} .
\]

(2.8)

The projected surface mass density, \( \Sigma \), is

\[
\Sigma(\vec{\theta}) = \int_{-\infty}^{\infty} \rho(D_A(EL)\vec{\theta}, \ell) d\ell ,
\]

(2.9)

where \( \ell \) denotes the line-of-sight coordinate, and

\[
\Sigma_{cr} \equiv \frac{c^2}{4\pi G} \frac{D_A(ES)}{D_A(EL)D_A(LS)} ,
\]

(2.10)

is the critical surface mass density. Physically, when \( \kappa > 1 \), the system satisfies the sufficient condition to form multiple images.

The absolute time delay, \( t \), is not an observable as we cannot directly observe the source without the lens, or the time difference between lensed and un-lensed images. However, if we have multiple images, we can compare the relative time delay between image pairs to calculate the time delay between two (or more) lensed images. Also, \( \phi \) can be modeled to satisfy observational constraints such as image positions, flux ratios and time-delay differences between multiple pairs of images; thus, we can obtain the time-delay distance.

In a differential form, the lens potential is related to the convergence field via

\[
\kappa(\vec{\theta}) = \frac{1}{2} \nabla^2 \psi(\vec{\theta}) ,
\]

(2.11)

where \( \nabla \) is a derivative in \( \vec{\theta} \) coordinates. Now we can write the lens equation which relates the observed image position to the source position in terms of the lens potential,

\[
\vec{\theta} - \vec{\beta} = \nabla \psi(\vec{\theta}) = \vec{\alpha},
\]

(2.12)

where \( \vec{\alpha} \) is the scaled deflection angle.
3 More realistic lenses

The analysis in section 2.1 assumes the simplest possible lens system: an SIS density profile with an isotropic velocity dispersion. While the SIS profile is widely used to model lens galaxies and is considered as a good approximation, several studies have shown that slopes of density profiles of individual galaxies show a non-negligible scatter from the SIS [13–16]. In this section, we consider an arbitrary power-law density profile (section 3.1) to show that, in such a model, we can still extract \( D_A(EL) \) from \( \Delta t_{i,j} \), \( \sigma^2 \), and image positions. We then show that the external convergence cancels out (section 3.2). We note that spherical symmetry is assumed throughout the paper.

3.1 Arbitrary slope of the spherical lens mass profile

Studies of early type galaxies (ETGs) as lenses have shown that the averaged total mass density profiles can be well approximated as a power-law, and also typical ellipticity of galaxies is fairly small [13–17]. Thus we allow the total mass density of a lens to follow a general power-law with spherical symmetry:

\[
\rho = \rho_0 \left( \frac{r}{r_0} \right)^{-\gamma'}.
\]  

(3.1)

The distribution becomes a SIS for \( \gamma' = 2 \) (section 2.1). The lens potential also has a power-law form, \( \psi(\theta) \propto \theta^l \), with \( l = 3 - \gamma' \). The scaled deflection, \( \tilde{\alpha} \), which is given by \( \nabla \psi = \tilde{\alpha} \), and the lens equation, \( \tilde{\beta} = \tilde{\theta} - \tilde{\alpha} \), gives

\[
\psi = \frac{1}{l} \tilde{\theta} \cdot \left( \tilde{\theta} - \tilde{\beta} \right).
\]  

(3.2)

Using this result in equation (2.5), we obtain the time delay between two images as

\[
\Delta t_{i,j} = \frac{1 + z_L}{2c} D_A(EL) D_A(ES) \left\{ \left( \tilde{\theta}_i - \tilde{\beta} \right)^2 - \left( \tilde{\theta}_j - \tilde{\beta} \right)^2 - \frac{2}{l} \left( \tilde{\theta}_i \cdot \left( \tilde{\theta}_i - \tilde{\beta} \right) - \tilde{\theta}_j \cdot \left( \tilde{\theta}_j - \tilde{\beta} \right) \right) \right\}.
\]  

(3.3)

From the geometry of the system, the lens equation and the definition of the angular diameter distance, the following relation between \( \tilde{\theta}, \tilde{\beta}, \) and \( \tilde{\alpha} \) holds:

\[
\tilde{\theta} - \tilde{\beta} = \tilde{\alpha} \equiv \frac{D_A(ES)}{D_A(ES)} \tilde{\alpha},
\]  

(3.4)

where \( \tilde{\alpha} \) is the deflection angle at the lens plane. We substitute \( \tilde{\theta} - \tilde{\beta} \) in equation (3.3) for \( \tilde{\alpha} \), and write

\[
\Delta t_{i,j} = D_A(EL) \left( \frac{1 + z_L}{2c} \right) \left\{ \left( \tilde{\alpha}_i + \tilde{\alpha}_j \right) \cdot \left( \tilde{\theta}_i - \tilde{\theta}_j \right) - \frac{2}{l} \left( \tilde{\theta}_i \cdot \tilde{\alpha}_i - \tilde{\theta}_j \cdot \tilde{\alpha}_j \right) \right\}.
\]  

(3.5)

The remaining task is to relate \( \tilde{\alpha} \) to observables. As the potential of a spherically symmetric system only has a radial component with respect to the center, \( \tilde{\alpha}, \tilde{\beta} \) and \( \tilde{\theta} \) have only radial components. Let us define \( \alpha \equiv |\tilde{\alpha}| \), which is the magnitude of the deflection angle at the lens plane. Under the power-law density profile model, \( \alpha \) is given by

\[
\alpha(b) = \frac{2GM(b)}{c^2 b} F(\gamma') \propto b^{-\gamma' + 2},
\]  

(3.6)
where $b$ is the physical separation between the lens and the point of the closest approach of the light ray, and

$$ F(\gamma') \equiv \frac{\sqrt{\pi} \Gamma \left[ \frac{1}{2} (-1 + \gamma') \right]}{\Gamma \left( \frac{\gamma'}{2} \right)} . \quad (3.7) $$

The derivation of this formula is given in appendix A.

Using the virial theorem, we obtain the radial velocity dispersion at a given radius $r$ as

$$ \sigma_r^2(r) = \frac{1}{2(\gamma' - 1)} \frac{GM(r)}{r} \propto r^{-\gamma' + 2} . \quad (3.8) $$

If the velocity dispersion is isotropic, $\sigma_r^2(r) = \frac{1}{3} \sigma^2(r)$, and the radial velocity dispersion is the same as the line-of-sight velocity dispersion, which is observable. As both $\alpha$ and $\sigma_r^2(r)$ scale with radii in the same way, we can write $\alpha(b)$ as

$$ \alpha = \frac{4(\gamma' - 1)}{c^2} F(\gamma') \sigma_r^2(b) = \frac{4(\gamma' - 1)}{c^2} F(\gamma') \sigma_r^2(r) \left( \frac{b}{r} \right)^{\gamma' + 2} . \quad (3.9) $$

We then obtain $D_A(EL)$ from equation (3.5) with $\alpha$ given by equation (3.9),

$$ D_A(EL) = \frac{c^3 \Delta t_{i,j}}{4 \pi \sigma^2_r(r)(1 + z_L)} \left( \Delta \bar{\theta}_{i,j} \right)^{-1} , \quad (3.10) $$

where\footnote{We use $\theta_i \cdot \theta_j = -1$ in reducing the vector dot products in equation (3.5) to the scalar products in equation (3.11).}

$$ \left( \Delta \bar{\theta}_{i,j} \right)^{-1} = \frac{2 \pi}{F(\gamma')(\gamma' - 1)} \left\{ \frac{2}{-\gamma' + 3} \left[ \theta_j \left( \frac{\theta_i}{\bar{\Theta}} \right)^{-\gamma' + 2} - \theta_i \left( \frac{\theta_j}{\bar{\Theta}} \right)^{-\gamma' + 2} \right] + (\theta_i + \theta_j) \left[ \left( \frac{\theta_i}{\bar{\Theta}} \right)^{-\gamma' + 2} - \left( \frac{\theta_j}{\bar{\Theta}} \right)^{-\gamma' + 2} \right] \right\}^{-1} , \quad (3.11) $$

and $\Theta$ is the angular position at which the velocity dispersion is measured, i.e., $r = \Theta D_A(EL)$. For $\gamma' = 2$, we obtain $\Delta \bar{\theta}_{i,j} = \theta_j - \theta_i$, and thus we can reproduce the result of the SIS model (equation (2.4)).

Equation (3.10) still supports the basic physical picture that the ratio of $\Delta t_{i,j}$ and $\sigma_r^2$ gives some effective physical size of the lens, and dividing it by the appropriate angular separation in the sky, $\Delta \theta_{i,j}$, gives the angular diameter distance. The main difference between the SIS and the power law density profiles is that, in the latter case, the velocity dispersion is a function of radii. In general, image positions are different from the points at which the velocity dispersion is measured. Thus, we need to correct for the mismatch of the exact locations of the velocity dispersion measurement and the image positions. This is why the $\left( \frac{\theta_i}{\bar{\Theta}} \right)^{-\gamma' + 2}$ term appears in the final expression of $D_A(EL)$: it scales the velocity dispersion such that we can get the potential at the image position. This requires us to measure (or model) the density slope, $\gamma'$, as well.

### 3.2 External convergence

In modeling realistic lens systems, one important factor to consider is the so-called “mass-sheet transformation (MST)”. MST is a subset of the source-position transformation [18].
Degeneracy exists, such that there are many mass models of the lens galaxy that can simultaneously reproduce most of the lensing observables, such as image positions and flux ratios, with different source positions [19]. This degeneracy constitutes one of the dominant sources of uncertainty in measuring the time-delay distance [7, 8, 18, 20]. In this subsection, we show that the effect of MST cancels out, leaving no effect on the inferred $D_A(EL)$.

Once we choose a model for the convergence field, $\kappa_{\text{model}}(\vec{\theta})$, that matches the observations, we transform $\kappa_{\text{model}}$ and $\vec{\alpha}$ to obtain a new convergence field, $\kappa_{\text{MST}}(\vec{\theta})$, and a new scaled deflection, $\vec{\alpha}_{\text{MST}}$, as

$$\kappa_{\text{MST}}(\vec{\theta}) = \lambda + (1 - \lambda) \kappa_{\text{model}}(\vec{\theta}),$$  
(3.12)$$
$$\vec{\alpha}_{\text{MST}}(\vec{\theta}) = \lambda \vec{\theta} + (1 - \lambda) \vec{\alpha}_{\text{model}}(\vec{\theta}),$$  
(3.13)$$
$$= \lambda \vec{\theta} + \vec{\alpha}_{\text{MST, lens}}(\vec{\theta}),$$  
(3.14)

where $\lambda$ is a constant which physically corresponds to the scaled convergence of a uniform sheet of mass external to the lens galaxy. In equation (3.14), we decompose the transformed deflection into two parts: a deflection from the lens, and that from the external convergence. We define $\vec{\alpha}_{\text{MST, lens}} \equiv (1 - \lambda) \vec{\alpha}_{\text{model}}$, whose meaning will be explained later in this subsection. To satisfy the lens equation (2.12) while leaving the image positions invariant, the source position must transform as

$$\vec{\beta}_{\text{MST}} = (1 - \lambda) \vec{\beta}_{\text{model}},$$  
(3.15)

which is why this transformation is a part of the family of transformation called the source-position transformation.

Considering the following relation among $\kappa$, $\phi$ and $\psi$,

$$\phi = \frac{1}{2} (\vec{\theta} - \vec{\beta})^2 - \psi,$$  
(3.16)$$
$$\nabla^2 \psi = 2 \kappa,$$  
(3.17)

the transformed Fermat potential of the $i$-th image, $\phi_{\text{MST},i}$, becomes

$$\phi_{\text{MST},i} = (1 - \lambda) \phi_{\text{model},i} - \frac{\lambda(1 - \lambda)}{2} |\vec{\beta}|^2 .$$  
(3.18)

Since the source position $\vec{\beta}$ is the same for all the images, the second term in equation (3.18) cancels out if we calculate the difference in the Fermat potential between two images $i$ and $j$. Thus, the difference, $\Delta \phi_{i,j}$, transforms as

$$\Delta \phi_{\text{MST},i,j} = (1 - \lambda) \Delta \phi_{\text{model},i,j} .$$  
(3.19)

As the time delay is directly proportional to the Fermat potential, we find that $\Delta t_{i,j}$ is simply increased by a factor of $1 - \lambda$ after the MST for fixed distances/cosmology.

If we assume that the physical origin of MST is an effective external convergence due to mass structures along the line of sight, $\kappa_{\text{ext}}$, we can identify $\lambda$ with $\kappa_{\text{ext}}$. In the following, we apply the MST to the power-law mass model and show that the inferred $D_A(EL)$ remains unaffected by $\kappa_{\text{ext}}$. We start first with the special case of SIS to gain intuition before considering the general power-law profile.
3.2.1 Singular isothermal sphere

Here we follow the steps from section 2.1, but with MST applied to it. From equation (3.12), the transformed density profile of the lens is

$$\rho_{\text{SIS},\text{MST}} = (1 - \kappa_{\text{ext}})\rho_{\text{SIS},\text{model}}. \quad (3.20)$$

Note that the original transformation equation (3.12) is written in terms of the convergence, $\kappa$; however, as the convergence and the density profile are proportional to each other (equation (2.8)), we transform the density in the same way as the convergence. To satisfy equation (2.1), the velocity dispersion must transform as

$$\sigma_{\text{MST}}^2 = (1 - \kappa_{\text{ext}})\sigma^2. \quad (3.21)$$

Equation (2.2) then becomes

$$\sigma_{\text{MST}}^2 = (1 - \kappa_{\text{ext}})\frac{\theta_E}{4\pi} \frac{D_A(ES)}{D_A(LS)} c^2 (1 + z_L) \Delta t_{\text{model},i,j}. \quad (3.22)$$

From equation (3.19), the time-delay equation (2.3) transforms as

$$\Delta t_{\text{MST},i,j} = (1 - \kappa_{\text{ext}})\left[\frac{2}{c^2} \frac{D_A(EL)}{D_A(LS)} \frac{D_A(ES)}{D_A(LS)} \left(\theta_j^2 - \theta_i^2\right)\right]. \quad (3.23)$$

and by combining the above two equations, we get

$$\Delta t_{\text{MST},i,j} = \frac{4\pi}{c^2} \sigma_{\text{MST}}^2 (1 + z_L) D_A(EL)(\theta_i - \theta_j), \quad (3.24)$$

in which $\kappa_{\text{ext}}$ cancels out. This equation is identical to equation (2.4), but with the transformed quantities, $\Delta t_{\text{MST},i,j}$ and $\sigma_{\text{MST}}^2$.

The reason is as follows. Suppose that we have a lens system which has a velocity dispersion of $\sigma^2$ and the time-delay difference of $\Delta t$. We then try to model this system by a lens plus an external convergence, $\kappa_{\text{ext}}$. Then, the modeled $\sigma$ and $\Delta t$ would be different from the original ones by a factor of $1 - \kappa_{\text{ext}}$, but the ratio of the two is invariant. As $D_A(EL)$ is proportional to the ratio of the two, we can measure the same $D_A(EL)$ as before, regardless of the existence of the external convergence.

3.2.2 Spherical power-law density profile

Now we study the effect of MST on the spherical power-law density profile lens galaxy model, following section 3.1. Combining the time-delay transformation with equation (3.5) yields

$$\Delta t_{\text{MST},i,j} = (1 - \kappa_{\text{ext}})\Delta t_{\text{model},i,j}$$

$$= (1 - \kappa_{\text{ext}}) D_A(EL) \frac{(1 + z_L)}{2c} \left[\alpha_{\text{model},i} + \alpha_{\text{model},j}\right] \left(\theta_i - \theta_j\right) - \frac{1}{i} \left(\theta_i - \theta_j\right) \left[\alpha_{\text{model},i} - \alpha_{\text{model},j}\right]. \quad (3.25)$$

Again, the density normalization of the lens galaxy, $\rho_0$, transforms as

$$\rho_{0,\text{MST}} = (1 - \kappa_{\text{ext}})\rho_{0,\text{model}}, \quad (3.26)$$
and thus among the total deflection angle $\alpha$, only a $(1-\kappa_{\text{ext}})$ fraction of it is from the lens, which is why we denoted this contribution as $\hat{\alpha}_{\text{MST,lens}} = (1-\lambda)\hat{\alpha}_{\text{model}}$ in equation (3.14). Using this in equation (3.25) yields

$$\Delta t_{\text{MST},i,j} = \frac{D_A(EL)}{2c}(1 + z_L) \frac{1}{2} \left( \hat{\alpha}_{\text{MST,lens},i} + \hat{\alpha}_{\text{MST,lens},j} \right) \cdot \left( \hat{\theta}_i - \hat{\theta}_j \right) - \frac{2}{l} \left( \hat{\theta}_i \cdot \hat{\alpha}_{\text{MST,lens},i} - \hat{\theta}_j \cdot \hat{\alpha}_{\text{MST,lens},j} \right).$$

(3.27)

As the measured velocity dispersion of the lens gives the estimate of the lens potential only, the relation between the deflection angle from the lens and the velocity dispersion does not change after the MST:

$$|\hat{\alpha}_{\text{MST,lens}}| = 4(\gamma' - 1) \sigma_r^2(R) \frac{b}{R} \left( \frac{b}{R} \right)^{-\gamma' + 2}.$$  

(3.28)

Thus, $D_A(EL)$ can be calculated from the original equation (3.10) even after the MST.

This is an important finding. In the previous studies of the time-delay distance to measure the Hubble constant, $\kappa_{\text{ext}}$ was the main obstacle in measuring $H_0$ precisely [7]. On the other hand, we have shown that $D_A(EL)$ measured from strong lensing, which combines the time-delay, the image position, and the velocity dispersion data, does not suffer from the effect of $\kappa_{\text{ext}}$.

4 Error formula and implications for B1608+686 and RXJ1131−1231

4.1 Aperture-averaged line of sight velocity dispersion

We do not measure the radial component of the velocity dispersion, $\sigma_r^2(r)$. Rather, we measure the luminosity-weighted line-of-sight velocity dispersion, $\sigma_p^2(R)$. We relate them using the following equation:

$$\sigma_p^2(R) \equiv I_p(R) \sigma_r^2(R) = 2 \int_R^\infty \left( 1 - \beta_{\text{ani}} \frac{R^2}{r^2} \right) \frac{\rho_*(r) \sigma_r^2(r) r dr}{\sqrt{r^2 - R^2}}.$$  

(4.1)

Here, $r$ denotes the three-dimensional radius, while $R$ denotes the projected radius. We shall use these two different radii notations for the rest of the paper. $\beta_{\text{ani}}$ is the effect of the velocity dispersion anisotropy, which will be studied in detail in section 5. In this section, we set $\beta_{\text{ani}} = 0$. The other functions are: $I_p(R)$ is the projected stellar distribution function, $\sigma_r^2(R)$ is the projected velocity dispersion and $\sigma_*(r)$ is given by equation (3.8). For a stellar density profile, $\rho_*$, we consider two profiles that are known to describe well the stellar light distributions of galaxies: the Hernquist profile and the Jaffe profile. These two different profiles would also allow us to assess the effect of luminosity weighting on $\sigma_p^2(R)$.

A generalized form of the stellar density distribution, which satisfies $\rho_* \propto r^{-\gamma}$ as $r \to \infty$, can be expressed as

$$\rho_*(r) = \frac{(3 - \gamma_*) I_0}{4\pi} a \frac{1}{r^{\gamma_*(r+a)^{4-\gamma_*}},} \quad \text{where } 0 \leq \gamma_* < 3,$$

(4.2)

following ref. [21]. The Hernquist profile corresponds to $\gamma_* = 1$ [22]:

$$\rho_*(r) = \frac{I_0 a}{2\pi r(r+a)^3},$$

(4.3)
where $I_0$ is a normalization and $a$ is a scale radius determined by $a = (2^{1/(3-\gamma_s)} - 1) r_{1/2}$ following ref. [21], where $r_{1/2}$ is the half-mass radius. Due to the projection effect, the two-dimensional half-light radius $R_{\text{eff}}$ is related to the three-dimensional half-mass radius $r_{1/2}$ as $r_{1/2} = 1.33 R_{\text{eff}}$ for the Hernquist profile, thus the scale radius $a = 0.551 R_{\text{eff}}$. The projected Hernquist distribution is known to provide a good fit for the stellar distribution of elliptical galaxies that follow the de Vaucouleurs law,

$$I_p(R) = \frac{I_0}{2 \pi a^2 (1 - s^2)^2} \left[ (2 + s^2) X(s) - 3 \right],$$  \hspace{1cm} (4.4)

where $s \equiv R/a$ is a scaled projected radius, and $X(s)$ is defined as

$$X(s) \equiv \begin{cases} 
\frac{1}{\sqrt{1-s^2}} \text{sech}^{-1} s & \text{for } 0 \leq s \leq 1 \\
\frac{1}{\sqrt{s^2-1}} \sec^{-1} s & \text{for } 1 \leq s < \infty 
\end{cases}.$$  \hspace{1cm} (4.5)

We then examine the case where the stellar density profile has a steeper slope at the center, by using the Jaffe model [23], which has $\gamma_s = 2$. We do not consider models with $2 < \gamma_s < 3$ as they fail to represent the basic physical properties of a galaxy, e.g. diverging potential / velocity dispersion at the center. In the Jaffe model, the stellar density profile becomes

$$\rho_s = \frac{1}{4\pi} \frac{a}{r^2(r+a)^2},$$  \hspace{1cm} (4.6)

and the projected surface brightness distribution, $I_p(R)$, becomes

$$I_p(R) = \frac{I_0}{4a^2 s} - \frac{I_0}{2\pi a^2 s^2} \frac{1}{1 - s^2} \left[ (s^2 - 2) X(s) + 1 \right],$$  \hspace{1cm} (4.7)

where for the Jaffe profile $r_{1/2} = 1.31 R_{\text{eff}}$ and $a = 1.31 R_{\text{eff}}$.

We note that both the Hernquist and Jaffe profiles for the stars are not single power-laws, and neither are dark matter distributions such as the Navarro, Frenk and White profile [24]. Stars and dark matter have different radial distributions in galaxies with the stars typically dominating over dark matter at the central parts and vice versa at outer parts. The contributions of stars and dark matter are often comparable around the effective radius. Despite the different radial distributions of stellar and dark matter, the total density profile of stars and dark matter is remarkably well described by a power-law within a few effective radius, as previous lensing and/or dynamical studies have shown (e.g., [13, 15, 17, 20]). Therefore, our use of the Hernquist/Jaffe profiles for the luminosity weighting to scale the velocity dispersion measured near the effective radius to the image positions is consistent with the use of a power-law for the total density profile. For a total density profile that is nearly isothermal, there is an inconsistency in the slope between the total density profile and the Hernquist profile at the center ($r \lesssim 0.1''$). However, the contribution of the enclosed mass from this central region to the total enclosed mass within either the Einstein radius or effective radius (approximately where we have lensing/dynamical measurements) is insignificant. Thus, the central slope inconsistency between the stellar and the total density has negligible impact on our lensing and dynamical analysis.

Ideally, we wish to measure the line-of-sight velocity dispersion profile as a function of projected radii. In practice, however, most of the observations do not allow us to spatially resolve the galaxy; rather they allow us to measure the luminosity-weighted, aperture-averaged
velocity dispersion inside an aperture of a fixed size \([25]\). We calculate the luminosity-weighted aperture-averaged projected velocity dispersion, \(\langle \sigma_p^2 \rangle_{ap} \), as follows:

\[
\langle \sigma_p^2 \rangle_{ap} \equiv \frac{\int_{ap} I_p \sigma^2 R \, dR \, d\theta}{\int_{ap} I_p R \, dR \, d\theta}.
\]

(4.8)

4.2 Analytic formula

In this section, we relate the statistical uncertainty in \(D_A\) to those of the observables, i.e., \(\Delta t\), \(\sigma_p^2\), and \(\gamma'\). (The effect of an anisotropic velocity dispersion will be discussed in detail in section 5.) Assuming that these observables are independently measured, we write the total uncertainty in \(D_A(EL)\), hereafter \(S_{D_A}\), as

\[
S_{D_A} = D_A \sqrt{\left(\frac{1}{\Delta t_{i,j}}\right)^2 S_{\Delta t}^2 + \left(\frac{1}{\sigma_p^2}\right)^2 S_{\sigma_p^2}^2 + \left(\frac{1}{\gamma'}\right)^2 S_{\gamma'}^2},
\]

where \(S_x\) is the measurement uncertainty in the variable \(x\). Since image positions, \(\theta_{i,j}\), are precisely measured, we do not include their uncertainties in this formula. In the following sections 4.3 and 4.4, we shall apply this formula to two lens systems, B1608+656 and RXJ1131−1231, respectively.

4.3 B1608+656

Figure 2 shows the image configuration of B1608+656 \([26]\). The information on image configuration is important as our formula applies only to a circularly symmetric case. Thus, the only image pairs we can use in this paper are the ones that are on the opposite sides of the lens center. More thorough analysis using all the data will be presented elsewhere (Suyu et al., in preparation). The data of B1608+656 are mostly from ref. \([7]\), but the image positions are calculated from the data given in ref. \([6]\), the time delays are from ref. \([27]\), and the redshifts are from refs. \([28, 29]\). For this system, the origin of the coordinates is set at the image A. The data are summarized as:

\[
\begin{align*}
z_L &= 0.6304 \\
z_s &= 1.394 \\
\bar{\theta}_A &= (0.0'', 0.0'') \\
\bar{\theta}_B &= (-0.7380'', -1.9612'') \\
\bar{\theta}_C &= (-0.7446'', -0.4537'') \\
\bar{\theta}_D &= (1.1284'', -1.2565'') \\
R_{\text{eff}} &= 0.58'' \\
\gamma' &= 2.08 \pm 0.03 \\
\langle \sigma_p^2 \rangle_{ap}^{1/2} &= 260 \pm 15 \text{ km/s} \\
\Delta t_{AB} &= 31.5^{+2.0}_{-1.6} \text{ days} \\
\Delta t_{CB} &= 36.0^{+1.5}_{-1.3} \text{ days} \\
\Delta t_{DB} &= 77.0^{+2.0}_{-1.6} \text{ days} \\
\Delta t_{CD} &= \Delta t_{CB} - \Delta t_{DB} = -41.0^{+2.5}_{-1.8} \text{ days}.
\end{align*}
\]

(4.10)
We use the CD pair. Also, as we write $D_A(EL)$ in terms of $\sigma_r(r)$ (e.g. 3.10), we normalize the radial velocity dispersion profile, $\sigma_r(r)$, using $\langle \sigma_p^2(R) \rangle_{ap}$ given by the observation and using equations (4.1) and (4.8). With these values, we find $D_A(EL) = 1485.7$ Mpc. For comparison, $D_A(EL)$ from the best-fit WMAP 7-year parameters is $D_A(EL) = 1423.3$ Mpc. We now use equation (4.9) to compute $S_{DA}$:

$$S_{DA} = D_A \sqrt{3.72 \times 10^{-3} + 1.33 \times 10^{-2} + 2.36 \times 10^{-3}},$$

(4.11)

where from the first term, each number indicates the fractional uncertainty in $D_A$ contributed by the time-delay measurement $\Delta t_{i,j}$, the line-of-sight velocity dispersion measurement $\sigma_p^2$, and the density profile index $\gamma'$. (Note that $S_{\sigma_p^2}/\sigma_p^2 = 2S_{\sigma_p}/\sigma_p$.) With this value, the total uncertainty, including all the terms in equation (4.11), is $S_{DA} = 0.14D_A$, i.e., 14% uncertainty. The dominant contribution comes from the uncertainty in $\sigma_p$, which gives $S_{DA} = 0.12D_A$.

### 4.4 RXJ1131−1231

In this section we repeat the same analysis as above, but with another well-studied strong lensing time-delay system, RXJ1131−1231, using data from refs. [30, 31] for the time delays and the redshifts, respectively, and from ref. [8] for the other quantities. The image configuration of the system is shown in figure 3. The data for this system are

$$z_L = 0.295$$
$$z_s = 0.658$$
$$\bar{\theta}_C = (4.411'', 4.011'')$$
$$\bar{\theta}_A = (2.383'', 3.412'')$$
$$\bar{\theta}_D = (5.494'', 4.288'')$$
$$R_{\text{eff}} = 1.85''$$
$$\gamma' = 1.95^{+0.05}_{-0.04}$$
$$\langle \sigma_p^2 \rangle_{ap}^{1/2} = 323 \pm 20 \text{ km/s}$$
$$\Delta t_{AB} = 0.7 \pm 1.4 \text{ days}$$
$$\Delta t_{DB} = 91.4 \pm 1.5 \text{ days}$$
$$\Delta t_{AD} = \Delta t_{AB} - \Delta t_{DB} = -90.7 \pm 2.1 \text{ days}.$$
We use the AD pair. Using these values, we find \( D_A(EL) = 813.33 \) Mpc, and \( D_A(EL) \) from the best-fit WMAP 7-year parameters is \( D_A(EL) = 876.5 \) Mpc. The total uncertainty in \( D_A(EL) \) is

\[
S_D = D_A \sqrt{5.36 \times 10^{-4} + 1.53 \times 10^{-2} + 1.46 \times 10^{-3}} = 0.13D_A.
\] (4.13)

The velocity dispersion alone gives \( S_D = 0.12D_A \). Therefore, we expect the existing data on these systems to yield \( D_A(EL) \) with \( 13 - 14\% \) precision per object, assuming the isotropic velocity dispersion. In the next section, we shall study the effect of the largest source of systematic uncertainty in our method: an anisotropic velocity dispersion, and how to reduce its effect in the estimation of \( D_A(EL) \).

5 Anisotropic velocity dispersion

The anisotropic stellar motion changes the relation between the potential and the observed line-of-sight velocity dispersion. As our method crucially relies upon knowing the potential depth, we must take into account the anisotropic velocity dispersion of stars. We do this by following ref. [7], which uses spherical Jeans modeling to relate the observed line-of-sight velocity dispersion to the mass distribution. We then study the effect of anisotropy on the aperture-averaged value of the velocity dispersion (section 5.1) as well as on the velocity dispersion measured at the so-called “sweet spot” (section 5.2). Finally, we use Monte Carlo simulations to compute the effect of anisotropy on the uncertainty in \( D_A(EL) \) (section 5.3).

5.1 Spherical Jeans equation

We solve the spherical Jeans equation for a given mass distribution (i.e., a power-law density profile) to obtain the three-dimensional radial velocity dispersion \( \sigma_r \),

\[
\frac{1}{\rho_*} \frac{d(\sigma_r^2 \rho_*)}{dr} + 2\beta_{\text{ani}} \frac{\sigma_r^2}{r} = -\frac{GM(\leq r)}{r^2}.
\] (5.1)

Here, the anisotropy function, \( \beta_{\text{ani}}(r) \), is chosen as the Osipkov-Merritt anisotropy [32, 33],

\[
\beta_{\text{ani}}(r) \equiv \frac{r^2}{\sigma_{\text{ani}}^2 + r^2} = 1 - \frac{\sigma_T^2(r)}{\sigma_r^2(r)},
\] (5.2)
where $\sigma_T(r)$ and $\sigma_r(r)$ are the velocity dispersions in the tangential and radial directions, respectively. Although the anisotropy is parametrized by a single variable, $r_{\text{ani}}$, under this specific model, we can model almost any velocity structures by linearly superimposing the solutions [33]. We then calculate $\sigma_p^2(R)$ from $\sigma_r^2(r)$ using equation (4.1), and $\langle \sigma_p^2 \rangle_{\text{ap}}$ using equation (4.8).

To quantitatively demonstrate the behavior of the anisotropic velocity dispersion, we again use the observations of B1608+656 introduced in section 4.3 for the analysis in this and the following sections.

In figure 4, we show the ratio of $\sigma_p^2(R)$ to the isotropic velocity dispersion, $\sigma_{\text{iso}}^2(R)$, with $a = 0.551 R_{\text{eff}}$ and $R_{\text{eff}} = 0.58''$ for the Hernquist profile. The isotropic velocity dispersion is a solution to the Jeans equation (5.1) with no anisotropy, $\beta_{\text{ani}} = 0$; thus, it is related more directly to $GM/R$. We have one free parameter, $n$, which parametrizes the anisotropic radius as

$$r_{\text{ani}} \equiv nR_{\text{eff}}. \tag{5.3}$$

For a given mass distribution of the lens, $\sigma_p^2(R)$ depends on $n$. We vary $n$ from 0.5 to 50 in logarithmic spacing. We find $\sigma_p^2(R)/\sigma_{\text{iso}}^2(R) \approx 1$ to within 10% at $R = R_{\text{eff}}$, except for the highly anisotropic case of $n = 0.5$ when the stellar distribution follows Hernquist profile.

In figure 5, we show the ratio of $\langle \sigma_p^2 \rangle_{\text{ap}}$ to $\sigma_{\text{iso}}^2(R_{\text{ap}})$ as a function of $n$, where $R_{\text{ap}}$ is fixed to 0.42''. In the left panel, this ratio reaches 26% for $n = 0.5$, and decreases as $n$ increases when the stellar distribution follows Hernquist profile. In the right panel, we show the same ratio for the Jaffe stellar distribution, with the ratio reaching 24% for $n = 0.5$. Overall the difference in $\langle \sigma_p^2 \rangle_{\text{ap}}$ between Hernquist and Jaffe distributions is small compared to the impact of the anisotropy. Therefore, for the remainder of the paper, we consider only the Hernquist distribution as a conservative model, where the dominant uncertainty on $\langle \sigma_p^2 \rangle_{\text{ap}}$ is due to the unknown anisotropy.

Since the inferred $D_A(EL)$ is proportional to the inverse of the isotropic velocity dispersion, having a large variation in the inferred isotropic velocity dispersion can cause a large
Figure 5. Ratio of $\langle \sigma_p^2 \rangle_{ap}$ to $\sigma_{iso}^2 (R_{ap})$, as a function of $n$. For the stellar density distribution, we use the Hernquist and Jaffe profiles in the left and right panels, respectively. The size of the aperture is fixed at $R_{ap} = 0.42''$. The upper limit of $n$, 5, is chosen since the velocity dispersion does not differ much from the isotropic case beyond $n$ of 5, while the lower limit, 0.5, is determined by observations (e.g. [34]) and radial instability arguments (e.g. [35, 36]). The unknown anisotropy dominates the uncertainty in $D_A(EL)$. Unfortunately, anisotropy is not directly observable, unless we have a three-dimensional velocity dispersion measurement. Clearly, a better approach is needed.

5.2 Sweet-spot method

It has been pointed out that, when the observations of the surface brightness profile and the velocity dispersion profile are available, one can find the so-called sweet spot, $R_{sweet}$, at which the effect of the anisotropic velocity dispersion on the mass determination is minimized [37]. Also see [38, 39]. The Osipkov-Merritt anisotropy model has an isotropic core and a radial envelope. However, as we observe the projected velocity dispersion, there are two components that play roles in the estimation of the observed velocity dispersion. The anisotropy changes the ratio between tangential and radial components of the velocity dispersion at a given radius, while the projection changes the magnitude of contributions from radial and tangential components. Quantitatively, at a fixed radius of observation $R$, $\sigma_p (R)$ has contributions from infinitely many shells with radii $r = R/\cos x$, where $x = [0, \pi/2]$. At each radius $r$ we can decompose the contributions to the projected velocity dispersion into tangential and radial components as $\sigma_T (r) \cos x$ and $\sigma_r (r) \sin x$, respectively. Due to the weighting by the trigonometric functions, at small $x$, contributions from the tangential component is bigger than that from the radial component, and vice versa at large $x$. Now, let us assume that the total velocity dispersion, $\sigma^2 (r) = \sigma_T^2 (r) + \sigma_r^2 (r)$, is the same for the isotropic and anisotropic model for a given galaxy mass, as it is proportional to the total kinetic energy. Then, when $r = R/\cos x$ is large, the tangential component is suppressed while the radial component is enhanced compare to the isotropic case, due to the anisotropy (since $\sigma_T (r)$ becomes small for large $r$ in equation (5.2)). As a result, in comparison to the isotropic case where $\sigma_T (r) = \sigma_r (r)$, anisotropic velocity dispersion shows $\sigma_p (R) > \sigma_{iso} (R)$ at small $R$, and $\sigma_p (R) < \sigma_{iso} (R)$ at large $R$. Thus, if we observe an anisotropic system, there exists a projected radius $R$ at which the transition from one to the other occurs, as we increase $R$ from the center of a galaxy to the outskirt of it. This transition radius is the sweet spot.

While the analytical derivation of $R_{sweet}$ has been done assuming a constant $\beta_{ani}$, the further study [40] shows that the method works for systems with a non-constant $\beta_{ani}$ as
well. The sweet spot can be determined from the brightness profile of a massive elliptical galaxy \cite{40}. It is close to the projected radius at which \( R \) satisfies \( d \ln I(R)/d \ln R = -2 \). For a Hernquist surface brightness profile, we find \( R_{\text{sweet}} \approx 0.78 R_{\text{eff}} \). It is also shown in \cite{37} that while the Sersic index changes from 1 to 12, \( R_{\text{sweet}} \) varies only about 0.3\( R_{\text{eff}} \), thus the sweet-spot radius is fairly insensitive to the luminosity profile. In figure 4, the sweet-spot radius is shown as the left vertical line. We find that the difference between projected velocity dispersions with various anisotropy parameters is minimum around \( R = 0.78 R_{\text{eff}} = 0.45'' \) with the data of B1608+656. It particularly reduces the effect of a highly anisotropic case with \( n = 0.5 \), compared to using \( \sigma_p^2(R) \) at the effective radius or the aperture-averaged \( \sigma_p^2 \). The uncertainty in the mass of massive ellipticals estimated from the sweet-spot method is claimed to be 5-7 per cent. Therefore, the best approach is to use spatially-resolved spectroscopic data of lens galaxies to obtain the velocity dispersion at the sweet spot.

5.3 Monte Carlo simulation

We use Monte Carlo simulations to study how much the velocity anisotropy inflates the uncertainty in \( D_A(EL) \), and how well we can mitigate it by using the sweet-spot method.

For two time-delay systems B1608+656 and RXJ1131–1231, we generate 11 discrete radial profiles of anisotropic velocity dispersion by solving the Jeans equation, with logarithmically spaced \( n = [0.5, 50] \). The effective radius and the density profile index \( \gamma' \) are fixed at the best-fit values given in sections 4.3 and 4.4. We randomly choose one profile from the set of different anisotropy parameters to create a mock galaxy. We then compute \( \sigma_p^2 \) from each mock galaxy in three ways: the aperture-averaged value \( \langle \sigma_p^2 \rangle_{\text{ap}} \) with the aperture size of 0.42'' for both systems, \( \sigma_p^2(R) \) with \( R = R_{\text{eff}} \), and \( \sigma_p^2(R) \) with \( R = R_{\text{sweet}} \). As the uncertainty in \( D_A(EL) \) is dominated by that of \( \sigma_p^2 \), we add a Gaussian random noise to \( \sigma_p^2 \) with variance of \( S_{\sigma_p}^2 = 2S_{\sigma_p}^2(S_{\sigma_p}^2 + 2\sigma_p^2) \). We then compute \( D_A(EL) \) from these simulated data with the best-fit values of the time-delay data and image positions given in sections 4.3 and 4.4. (We do not add noise to time delays or image positions.) While our simulated galaxies have anisotropic velocity dispersions, we use the isotropic velocity dispersion model to calculate \( D_A(EL) \). In this way we can quantify the effect of our ignoring anisotropic velocity dispersion by marginalizing over it.

Figures 6, 7, and 8 show the distributions of \( D_A(EL) \) obtained from mock B1608+656 realizations using \( \langle \sigma_p^2 \rangle_{\text{ap}} \), \( \sigma_p^2(R_{\text{eff}}) \), and \( \sigma_p^2(R_{\text{sweet}}) \), respectively. The solid and dashed histograms in each panel show the realizations with the isotropic and anisotropic velocity dispersions, respectively. The former realizations are used to check validity of our simulations, as well as to make a direct assessment of the effect of anisotropy. The vertical dotted lines show \( D_A(EL) = 1485.7 \) Mpc that we obtained in section 4.3.

We summarize the results from the analysis on B1608+656 and RXJ1131–1231 in tables 1 and 2, respectively. The uncertainties in \( D_A(EL) \) from isotropic simulations (interpreted by the isotropic model) agree with the analytical estimates given in sections 4.3 and 4.4. On the other hand, those from anisotropic simulations (again interpreted by the isotropic model) show significantly larger uncertainties when \( \langle \sigma_p^2 \rangle_{\text{ap}} \) or \( \sigma_p^2(R_{\text{eff}}) \) is used. Fortunately, using \( \sigma_p^2(R_{\text{sweet}}) \) eliminates most of the inflation of the uncertainty due to velocity anisotropy.

Figure 8 shows that the peak is shifted in the anisotropic case in comparison to the isotropic case, while in figure 7 the peak remains at the same position. This is due to the marginalization of the anisotropy. In figure 4, we choose 6 different \( n \) values that are spaced logarithmically, and choose two radii \( (R_{\text{eff}} \) and \( R_{\text{sweet}} \)) to calculate the \( D_A \) distributions for
Figure 6. Simulated distribution of $D_A(EL)$ to B1608+656. The solid and dashed histograms show the distributions with the isotropic and anisotropic simulations, interpreted by the isotropic model. We use the aperture averaged velocity dispersion, $\langle \sigma^2_p \rangle_{ap}$, with the aperture size of 0.42$''$. The standard deviation of the velocity dispersion used in simulations is 15 km/s. The fractional uncertainty in $D_A$ is 11.5% in the case of isotropic velocity dispersion model, while in the case of anisotropic velocity dispersion model it is 16.9%.

Figure 7. Same as figure 6, but with $\sigma^2_p(R_{\text{eff}})$ and $R_{\text{eff}} = 0.58''$. The fractional uncertainty in $D_A$ is 11.7% in the case of isotropic velocity dispersion model, while in the case of anisotropic velocity dispersion model it is 14.5%.

both the isotropic and anisotropic cases. At $R_{\text{sweet}}$, the scatter between the curves is smaller compare to that at $R_{\text{eff}}$; however, at $R_{\text{sweet}}$, the curves are also shifted toward higher velocity dispersions compared to the isotropic case. As a result, the whole distribution of $D_A$ is shifted toward lower values. On the other hand, at $R_{\text{eff}}$, while the scatter is larger, there is no systematic change in $\sigma^2_p$ relative to $\sigma^2_{iso}$ (i.e. among 6 values of $n$, two give $\sigma^2_p$ larger than the $\sigma^2_{iso}$, two give smaller, and the other two give $\sigma^2_p$ almost identical to the $\sigma^2_{iso}$ value). As
Figure 8. Same as figure 6, but with $\sigma_p(R_{\text{sweet}})$ and $R_{\text{sweet}} = 0.45''$. The fractional uncertainty in $D_A$ is 11.9% in the case of isotropic velocity dispersion model, while in the case of anisotropic velocity dispersion model it is 12.3%.

|     | Isotropic | Anisotropic |
|-----|-----------|-------------|
| $R_{\text{ap}}$ | 11.5%     | 16.9%       |
| $R_{\text{eff}}$ | 11.7%     | 14.5%       |
| $R_{\text{sweet}}$ | 11.9%     | 12.3%       |

Table 1. Expected fractional uncertainty in $D_A(EL)$ to B1608+656.

|     | Isotropic | Anisotropic |
|-----|-----------|-------------|
| $R_{\text{ap}}$ | 12.5%     | 15.1%       |
| $R_{\text{eff}}$ | 12.4%     | 14.8%       |
| $R_{\text{sweet}}$ | 12.5%     | 12.6%       |

Table 2. Expected fractional uncertainty in $D_A(EL)$ to RXJ1131−1231.

As the distribution of $D_A$ depends on the choice of the anisotropy model as well as on the range/selection of $n$, we study another anisotropy parameterization to see the robustness of the results against the choice of parameterization in the next section.

5.4 Agnello et al. (2014) parameterization

To show that the sweet spot is not a unique characteristic of Osipkov-Merritt anisotropy, we repeat the same analysis using a different spatially-varying anisotropy parameter, $\beta_{\text{ani}}(r)$, from ref. [41]:

$$\beta_{\text{ani}}(r) = \frac{\beta_{\text{in}} r^2 + \beta_{\text{out}} r_a^2}{r^2 + r_a^2}.$$
Two additional parameters, $\beta_{\text{in}}$ and $\beta_{\text{out}}$, are added to the Osipkov-Merritt anisotropy. We follow ref. [41] and adopt flat priors on $\beta_{\text{in}} = [-0.6, 0.6]$ and $\beta_{\text{out}} = [-0.6, 0.6]$, while the anisotropic radius, $r_a$, is scaled in the same way as in the Osipkov-Merritt model (equation (5.3)).

The resulting velocity dispersion profiles are shown in figure 9. Near the sweet spot, the fractional uncertainty in the velocity dispersion becomes as small as 15%. Also we note that the deviation from the isotropic velocity dispersion is not skewed at the sweet spot, which keeps the peak of the posterior distribution of $D_A$ at the same place as for the isotropic dispersion model. The posterior distribution calculated at the sweet-spot radius is shown in figure 10. We find that the uncertainty on angular diameter distance using this parametrization is about 13% for B1608+656, and 14% for RXJ1131−1231, comparable to those in section 5.3.

6 Conclusion

In this paper, we have shown that we can determine $D_A(EL)$ to strong lens systems with time delays. The underlying physics is simple; thus, this method offers a robust determination of $D_A(EL)$ to individual systems. The key advantage of this method is that the external convergence does not affect the distance determination. The uncertainty in the inferred $D_A(EL)$ is dominated by that in the velocity dispersion and its anisotropy. The effect of anisotropy can be minimized by measuring the velocity dispersion at the sweet-spot radius.

The existing data on B1608+656 and RXJ1131−1231 should yield $D_A(EL)$ with 17% and 15% precision, respectively. If we use the velocity dispersions at the sweet-spot radii, the precision improves to about 13%. In figure 11, we show the expected fractional uncertainty in $D_A(EL)$ to B1608+656 as a function of the uncertainty in the velocity dispersions, $\sigma$. The $\sigma$ at the sweet-spot radius measured with 260 ± 7 km/s corresponds to $\sigma^2$ measured...
Figure 10. Same as figure 8, but with the anisotropic velocity dispersion parametrization given by equation (5.4). Note that we use more realizations here in comparison to the previous analysis, as the parameter combination is 169 times as much as the one from Osipkov-Merritt parameterization, due to two additional parameters. As a consequence, the result for the isotropic case is slightly different from figure 8. The fractional uncertainty in $D_A$ is 12.1% in the case of isotropic velocity dispersion model, while in the case of anisotropic velocity dispersion model it is 13.0%.

Figure 11. Expected fractional uncertainty in $D_A(EL)$ to B1608+656 as a function of the uncertainty in $\sigma$ in units of km/s. The dashed, dotted, and solid lines are for $\sigma = \langle \sigma_p \rangle^{1/2}$, $\sigma_p(R_{\text{eff}})$, and $\sigma_p(R_{\text{sweet}})$, respectively.
with 5% precision. This yields $D_A(EL)$ with 7% precision, after marginalizing over velocity anisotropy. We show the robustness of our results using two different parameterizations of $\beta_{ani}(R)$, but a further study may be needed for more general cases.

This paper describes the basic idea and presents an estimate of what we can do with the existing data. Since we assumed spherical density profiles, our analysis is not precise enough to yield the best determinations of $D_A(EL)$ to B1608+656 and RXJ1131−1231. The method presented in this paper has been implemented in the full analysis pipeline used by refs. [7, 8], and the results will be reported in a future publication (Suyu et al., in preparation).

Acknowledgments

IJ would like to thank Karl Gebhardt for his support and encouragement, and Eugene Churazov, Adriano Agnello, Matthew Auger, Simona Vegetti, Stefan Hilbert, Chiara Spiniello, Natalia Lyskova, and Edward Robinson for useful discussions. EK would like to thank Phil Marshall and Masamune Oguri for useful discussions, and Stefan Hilbert for his clear lecture on strong lenses. SHS would like to thank Adriano Agnello, Matthew Auger and Matteo Barnabè for helpful discussions. Funding for this work has been provided in part by Texas Cosmology Center (TCC). TCC is supported by the College of Natural Sciences and the Department of Astronomy at the University of Texas at Austin and the McDonald Observatory.

A Deflection angle of an arbitrary power-law density profile

We derive the expression for a deflection angle near a galaxy with the density profile following a power-law with arbitrary density profile index. When the density profile is given as equation (3.1), the mass contained within a radius $r$ is

$$M(r) = \frac{4\pi \rho_0 r^\gamma' r^{-\gamma'} dr}{-\gamma' + 3} = \frac{4\pi \rho_0 r^\gamma'}{3 - \gamma'} r^{-\gamma' + 3},$$

(A.1)

which yields an acceleration given by

$$\bar{g}(\bar{r}) = -\frac{4\pi G \rho_0 r^\gamma' \bar{r}^{-\gamma'} \bar{r}}{3 - \gamma'} r^{-\gamma' + 3},$$

(A.2)

on the test mass located at the radius $r$. According to the post-Newtonian approximation in General Relativity, the rate of change of the direction of the velocity vector of the test mass, $\ddot{u}$, is given as

$$c^2 \frac{d\ddot{u}}{dt} = -2\ddot{u} \times (\ddot{u} \times \bar{g}).$$

(A.3)

We define a new parameter $\alpha$ to be the angle by which the light is deflected as it passes near the lens galaxy. In the cases we consider, the deflection angle will be small. Thus, we can choose coordinates such that the path of the light is roughly along the x-axis, and the line connecting the center of the lens galaxy to the point of the closest approach is along the y axis. Again, because the deflection angle is small, we use the thin lens approximation, namely, light is bent sharply at the closest approach to the lens. Thus, the separation from the center of lens to the light path, $r$, becomes $r^2 = b^2 + x^2$, and, more importantly, $\ddot{u} \times (\ddot{u} \times \bar{r}) = -c^2 \bar{b}$. 

\[ -21 - \]
We define the deflection angle at the lens plane, \( \hat{\alpha} \), as the total change in the photon propagation direction, and the magnitude of the deflection angle as \( \alpha \). Then, \( \hat{\alpha} \equiv \frac{1}{c} \int d\vec{u} = -\alpha \frac{\vec{r}}{r} \) (A.4), where the minus sign indicates that the deflection happens toward the lens center. Then \( \alpha \) becomes

\[
\alpha = \frac{8\pi G \rho_0 r_0^{\gamma'}}{c^2 (3 - \gamma')} \int_{-\infty}^{\infty} b r^{\gamma'} dx
\]

\[
= \frac{8\pi G \rho_0 r_0^{\gamma'}}{c^2 (3 - \gamma')} b \int_{-\infty}^{\infty} \frac{dx}{(x^2 + b^2)^{\gamma'/2}}
\]

\[
= \frac{8\pi G \rho_0 r_0^{\gamma'}}{c^2 (3 - \gamma')} b^{2-\gamma'} \sqrt{\pi} \left[ \frac{1}{2} (-1 + \gamma') \right] \Gamma \left( \frac{\gamma'}{2} \right),
\]

assuming \( \gamma' > 1 \).
