THE CAT WITH NEUROLOGICAL MANIFESTATIONS OF SYSTEMIC DISEASE

Key conditions impacting on the CNS

Marc Kent

Diseases with neurological consequences

There are a number of systemic disorders in cats that can result in neurological consequences. In most such disorders, signs of systemic disease overshadow the neurological deficits. In some systemic disorders, neurological signs dominate the clinical picture.

Four important systemic diseases with neurological consequences are feline infectious peritonitis (FIP), toxoplasmosis, hypertension and hepatic encephalopathy (HE).

Feline infectious peritonitis

Feline infectious peritonitis is a fatal viral infection of wild and domestic Felidae worldwide that is caused by a mutant variant of a ubiquitous feline enteric coronavirus (FECV). The clinical syndrome of immune-mediated vasculitis and pyogranulomatous inflammation that has become known as FIP was first described in 1963. Later a viral etiology, feline infectious peritonitis virus (FIPV), was identified and classified as a coronavirus. Although it was initially believed that FIPV and FECV were distinct entities, it is now known that FIPV develops out of spontaneous mutation of FECV within an infected cat. Therefore, the antigenicity and genome of FIPV is nearly identical to FECV but FIPV possesses a very different pathogenicity. Throughout the remainder of this article, the term feline coronavirus (FCoV) will be used when referring to all feline coronaviral infections, and the terms FECV and FIPV will be used to denote specifics regarding enteric infection and FIPV infections, respectively.

Distributed worldwide, FCoV is a single-stranded RNA virus belonging to the genus Coronavirus of the family Coronaviridae. Consequently, FIPV infection represents a disease with worldwide significance. While the systemic consequences of FIPV infection are clearly significant, the focus of the following discussion is on the impact of FIPV on the nervous system.

Practical relevance A number of systemic diseases are associated with neurological deficits. Most systemic diseases that impact on the nervous system result in multifocal neurological signs; however, isolated deficits can also be observed. This article reviews the clinical signs, pathophysiology, diagnosis, treatment and prognosis of four important systemic diseases with neurological consequences: feline infectious peritonitis, toxoplasmosis, hypertension and hepatic encephalopathy.

Clinical challenges Early recognition of systemic signs of illness in conjunction with neurological deficits will allow for prompt diagnosis and treatment. While neurological examination of the feline patient can undoubtedly be challenging, hopefully the accompanying articles in this special issue will enable the clinician to approach these cases with more confidence.

Evidence base The veterinary literature contains numerous reports detailing the impact of systemic disease on the nervous system. Unfortunately, very few references provide detailed descriptions of large cohorts of affected cats. This review summarises the literature underpinning the four key diseases under discussion.
Knowledge of the epidemiology of FCoV infection is important in order to understand the pathogenesis of FIPV. Feline coronavirus infection is virtually endemic, with studies revealing that:

- Approximately 50% of cats in the United States and Europe have antibodies against FCoV.3
- In Australia, the seroprevalence in owned cats is approximately 34%.7
- In the UK, 82% of show cats, 53% of breeding cats and 15% of single-cat homes have anti-FCoV antibodies;8
- In Italy, the seroprevalence is 82% in cats from breeding colonies, shelters and homes;9
- In Switzerland, similarly 80% of breeding cats, and 50% of free-roaming cats, test positive for anti-FCoV antibodies.10

The significance of this worldwide distribution relates to the fact that FIPV is the result of spontaneous mutation of FECV, which means that cats worldwide are susceptible to developing FIP.6 Despite this, approximately 5% of cats in mulicat homes and a smaller percentage of cats in single-cat homes develop FIP.3,11,12 Notably, it is young cats and immunosuppressed cats that are most susceptible to developing FIP. In addition, certain purebreed cats, specifically the Birman, Ragdoll, Bengal, Rex, Abyssinian and Himalayan breeds, have a greater risk of developing FIP, which suggests a genetic influence on susceptibility.13 Transmission of FCoV is through infected fecal material via the orofecal route, leading to enteric infection. Enteric FCoV infection typically results in inappetence and/or mild gastrointestinal signs such as vomiting and diarrhea. Infected cats shed FECV for up to 10 months post infection; thereafter infected cats shed virus intermittently or continuously, serving as chronic carriers and thereby perpetuating reinfection of other individuals.14 As with all coronaviruses, FECV undergoes a high rate of mutation. The degree of mutation, and therefore the development of a mutation leading to FIP, appear greater in susceptible individuals as well as in individuals with a high viral load.15,16 In part, this may explain the fact that more than 50% of cats with FIP are under a year of age.3

Pathogenesis

The initial step in the pathogenesis of FIP is the mutation of FCoV, in the process of which the virus gains the ability to replicate within macrophages. Once this occurs, the virus can be disseminated throughout the body. Ultimately, FIP is an immune complex disease that is a consequence of virus or viral antigens complexed with antiviral antibodies.16 After distribution by macrophages, the virus may enter tissue and replicate, resulting in attraction of neutrophils and macrophages and leading to granuloma formation.16 Alternatively antigen–antibody complexes may adhere to the vasculature, fix complement and attract macrophages, resulting in granuloma formation.17 Regardless of the exact mechanism, the combination of macrophage infiltration and complement fixation leads to the release of inflammatory cytokines and vasoactive amines; these cause vasculitis resulting in pyogranulomatous inflammation and exudation of protein-rich fluid from capillaries.

Clinical signs

Clinical signs of FIP are often vague (Fig 1), with affected cats displaying non-specific systemic signs including intermittent fever, lethargy, anorexia, vomiting, diarrhea and weight loss. Physical examination may disclose abdominal effusion, abdominal lymphadenopathy, and irregular and asymmetrical kidneys.

Neurological signs may be observed in approximately 30% of affected cats,18-21 either alone or in conjunction with systemic signs. Most cats with neurological signs have non- effusive FIP and typically display multifocal neurological signs.18-21 Affected cats often demonstrate signs consistent with central vestibular disease including head tilt, vestibular ataxia, abnormal nystagmus and postural reaction deficits.20

Pathology

Grossly, the meninges may appear thickened and opaque, especially those overlying the ventral aspect of the brain.18 Occasionally, no gross abnormalities are observed. In general, lesions are surface-oriented, distributed over the external leptomeningeal and ependymal surfaces of the nervous system, with the caudal and ventral aspects of the brain being most severely affected.18 Histologically, typical pyogranulomatous inflammatory infiltrates are observed. Lesions comprise meningitis, ependymitis and periventriculitis.

Neurological signs may be observed in approximately 30% of cats with FIP, either alone or in conjunction with systemic signs.

**Neurological signs**

- **Neurological signs may be observed in approximately 30% of affected cats,**18-21 **either alone or in conjunction with systemic signs.** Most cats with neurological signs have non- effusive FIP and typically display multifocal neurological signs.20 Abnormal mental state and behavior, seizures, ataxia, deficits in cranial nerve function, and varying degrees of tetra- or paraparesis are among the signs seen.18-21 **Affected cats often demonstrate signs consistent with central vestibular disease including head tilt, vestibular ataxia, abnormal nystagmus and postural reaction deficits.20**
Since FIP is an immune-mediated disease process, therapy has been directed at immunosuppression and/or immunomodulation with the goal of providing symptomatic care. Immunosuppressive therapy using corticosteroids (prednisone at 2–4 mg/kg/day) may allow mildly affected cats to maintain an acceptable quality of life for weeks to months. In addition to corticosteroids, a wide array of drugs including chemotherapy agents (cyclophosphamide and melphalan), an antiviral (ribavirin), a thromboxane synthetase inhibitor (ozagrel hydrochloride) and a variety of immunomodulating drugs (promodulin, human interferon-α, Propionibacterium acnes, and feline interferon-ω) have been investigated.36

The interpretation of results from most studies has been hindered by a lack of control groups and the difficulty in establishing a definitive diagnosis of FIP in treated cats.36 Still, most therapeutic trials have failed and, disappointingly, an effective treatment regime remains elusive.

Consisting primarily of lymphocytes, macrophages, and varying numbers of plasma cells forming perivascular cuffs,18 Subependymal periventricular infiltrate may obstruct the mesencephalic aqueduct leading to obstructive hydrocephalus. Similarly, obstruction of the central canal of the spinal cord may lead to hydromyelia. Occasionally, infiltrate extends into the superficial neuropil and cranial nerve roots.18

**Diagnosis**

Hematology in affected cats usually reveals a normocytic, normochromic, non-regenerative anemia, leukocytosis consisting of a neutrophilia, and lymphopenia.22 Approximately 50% of cats with the effusive form and 70% of cats with the dry form have increased serum proteins, primarily comprising a hyperglobulinemia.23 Protein electrophoresis discloses a polyclonal gammapathy, mainly involving the γ-globulins.24 Other biochemical changes may be observed depending on the severity of involvement of other organ systems including abnormal liver enzyme, bilirubin, blood urea nitrogen and creatinine levels.25

Although common clinicopathologic abnormalities in affected cats have been defined, changes in routine hematology and biochemical evaluations are often non-specific. Consequently, establishing a definitive ante mortem diagnosis of FIP is extremely challenging.26 Definitive diagnosis can only be achieved through histopathological identification of pyogranulomatous inflammation within tissue coupled with identification of the virus.16 Viral identification in tissue samples can be performed using immunohistochemistry or through PCR testing. However, there are several tests that may help support a presumptive ante mortem diagnosis. Importantly, interpretation of results from such tests should be evaluated in conjunction with clinical signs and results of other diagnostics. Taken outside the context of signs and other clinicopathologic data, most tests are unable to provide a definitive diagnosis.

When present, effusions should be analyzed. Typically, effusion from an affected cat should be consistent with a modified transudate.3 Cats with neurological signs should undergo magnetic resonance imaging (MRI) of the brain. This may disclose hydrocephalus.18 Additionally, T2-weighted and T2-weighted FLAIR images may reveal periventricular hyperintensities consistent with periventriculitis.18 Although these findings are not pathognomonic, MRI of the brain should be pursued in order to eliminate the potential that clinical signs may be a consequence of a disease process other than FIPV.

Analysis of cerebrospinal fluid (CSF) often reveals increased protein content (50–350 mg/dl) with a pleocytosis consisting of neutrophils, lymphocytes and macrophages.20,27,28

The evaluation of FCoV antibody titers (often erroneously referred to as an ‘FIP titer’) in blood and other fluids has been extensively studied. However, despite years of investigation, caution should be exercised when interpreting FCoV antibody titers in blood and effusions as high titers can be observed in healthy cats and low to absent titers in affected cats.3 Feline coronavirus antibody titers can be measured in CSF and may correlate with the

**KEY POINTS: FELINE INFECTIOUS PERITONITIS**

- Approximately 30% of cats with FIPV infection demonstrate neurological signs such as abnormal mentation, seizures, vestibular dysfunction, and varying degrees of para- and tetraparesis.
- Definitive diagnosis requires observation of pyogranulomatous inflammation and identification of virus in tissue. A presumptive diagnosis is made by utilizing a variety of clinicopathologic data including imaging, biochemical analysis, measurement of serum α-glycoprotein, FCoV antibodies, and PCR testing.
- FIPV is fatal and treatment is mainly palliative.
presence of neurological FIPV. Cerebrospinal fluid FCoV antibody titers correlate with serum FCoV antibody titers but, most importantly, elevated CSF FCoV antibody titers may also be observed in cats affected by neurological diseases other than FIP.

While PCR assays can be performed on blood and effusions in affected cats, they are unable to distinguish between the mutated FCoV causing FIP, and the non-pathogenic FCoV. In addition, healthy cats can be viremic with FCoV. Therefore, PCR identification of virus in blood or effusions does not provide a definitive diagnosis. While its application in CSF has not been studied, PCR identification of virus in CSF may allow a definitive diagnosis of FIP.

Measurement of serum α1-acid glycoprotein (AGP), an acute phase protein that increases during inflammation, has been used in the diagnosis of FIP. In cats with signs and clinicopathologic data highly suggestive of FIP, elevation in serum AGP provides strong supportive evidence of FIPV infection. However, AGP may also increase in other conditions associated with inflammation, such as feline immunodeficiency virus (FIV) infection, or in cats with a high viral load of FECV, which may limit its potential as a diagnostic tool for FIP.

**Prognosis**

Unfortunately, the prognosis for cats with FIP is grave as all affected cats succumb to the disease. To date, no therapy has been shown to alter the eventuality of humane euthanasia or death of affected cats.

**Toxoplasmosis**

Toxoplasmosis is caused by an obligate intracellular protozoan parasite, Toxoplasma gondii. The definitive hosts are the domestic cat and other Felidae. Many mammals can become infected with T. gondii and serve as intermediate hosts; however, fecal shedding of infective oocysts occurs only in cats.

Systemic and ocular toxoplasmosis have been well described in cats. The emphasis in the following discussion is on central nervous system (CNS) toxoplasmosis.

**Life cycle and transmission**

There are three methods of transmission of T. gondii: fecal–oral, ingestion of tissue cysts, and congenital. Reproduction of the organism can involve both a sexual and asexual phase. The asexual phase occurs in many mammals and birds, which serve as intermediate hosts. As the definitive host, the sexual phase of the life cycle can only occur in cats and it does so within the intestinal tract. As a result, unsporulated oocysts, which are non-infectious, are passed in the feces. These oocysts require 1–5 days for sporulation to occur, at which point they become infectious. Ingestion of sporulated oocysts by another cat begins another cycle.

Toxoplasma gondii also displays an extra-intestinal life cycle. After infectious oocysts have been ingested, the organism is capable of penetrating the wall of the intestinal tract and disseminating to multiple organs. Within these other organs, asexual reproduction occurs, giving rise to tissue cysts – bradyzoites (so named given their slow replication) and tachyzoites (in which replication is rapid). Ingestion of bradyzoites in tissue is probably responsible for the majority of infections. In cats it can result in intestinal replication, while ingestion of bradyzoites by other animals can only lead to extraintestinal infection. Ingestion of infectious organism during gestation can also lead to congenital infection.

Cysts that form as a result of extraintestinal infection are likely to persist for life. Encysted bradyzoites are the most probable source of continual release of antigen and reactivation of infection. Reactivation of infection is thought to occur secondarily to immunosuppression. Cats infected with FIV appear to be predisposed to the development of acute toxoplasmosis. There appears to be a high seroprevalence of T. gondii infection in cats co-infected with FIV. The significance of this relationship is unknown as the seroprevalence of T. gondii infection in FIV-infected cats is similar to that in the general population. Immunosuppression as a result of ciclosporin therapy has also led to acute toxoplasmosis. With the availability of renal transplantation in cats, the role of immunosuppression in reactivation of infection and the development of clinical disease has gained importance.

**Clinical signs**

Clinical infection with T. gondii is not common in cats. Infections can be considered acute or chronic. Acute toxoplasmosis typically affects younger cats. The most common clinical signs are anorexia, lethargy, fever, dyspnea and sudden death. Chronic toxoplasmosis typically affects older cats and manifests over weeks to months. Signs are similar to acute infection and may include vomiting, diarrhea, anorexia, weight loss, fever and icterus.
Clinical signs reflecting organ involvement include lymphadenopathy, myocardial disease, pancreatitis, hepatitis, anterior uveitis and chorioretinitis.41,42,49-51,53,54

**Central nervous system involvement occurs in almost all clinically affected cats.**50 Neurological signs typically reflect a multifocal distribution and include hypothermia, behavioral changes, seizures, ataxia, blindness, anisocoria, torticollis, vestibular disease, muscle hyperesthesia, and paresis/paralysis.21,42,50,55-58 Central nervous system signs may or may not occur in conjunction with systemic disease. Occasionally, cats may present with signs consistent with focal disease such as seizures or paralysis related to spinal cord disease.55,56,59

**Diagnosis**

The diagnosis of clinical toxoplasmosis can be challenging. Hematologic findings are non-specific, often consisting of non-regenerative anemia, neutrophilic leukocytosis, lymphocytosis and monocytosis.41,42,50 Biochemical abnormalities generally reflect organ involvement and include azotemia, elevation in liver enzymes, hyperbilirubinemia and hyperproteinemia.41,52,50 Thoracic radiographs may show a diffuse interstitial to bronchial pattern in which infiltrate may coalesce into areas of patchy alveolar patterns (Fig 2).49-51,60

Cerebrospinal fluid analysis typically reveals a mild lymphocytic pleocytosis predominantly, although other cell types may be observed; protein may be elevated to up to 149 mg/dl.59 Neutrophilic pleocytosis has also been reported.58

With the exception of identifying T gondii in tissue, no single test provides a definitive diagnosis. A presumptive diagnosis is based on a combination of clinical signs, evidence of recent or active infection (gained via serology for immunoglobulins or immune complexes, or PCR), exclusion of other disease processes, and response to therapy.39

Serology for the detection of IgG and IgM anti-T gondii antibodies is widely used.61 After experimental inoculation, an IgM response is detected in 1-3 weeks and an IgG response in 2-4 weeks. Immunoglobulin M responses peak within 3 weeks and persist for 3-16 weeks. In cats co-infected with FIV, there is a delayed conversion from an IgM to an IgG response.62 Unfortunately, an IgM response does not necessarily correlate with active disease as occasionally IgM responses can be detected in clinically normal cats with chronic infection. Likewise, a single high IgG response does not predict active disease, as IgG responses can last up to 6 years.63 A rising titer is strongly suggestive of active disease, however, and maximal titers are reached within 2-3 weeks.63 In practice, given the insidious nature of the disease many cats have reached maximal immune responses by the time they are examined by a veterinarian, making documentation of a rising titer difficult.61

Theoretically, identification of an immune response in the CNS, an immunoprivileged site, would suggest infection. However, immunoglobulins may extravasate from the blood into the CSF in other inflammatory diseases that disrupt the blood-brain barrier. Defining a ratio between serum and CSF IgG responses may help eliminate the possibility of passive cross over of antibodies secondary to another disease that compromises the integrity of the blood-brain barrier. A serum:CSF IgG response > 1 suggests local CNS production of immunoglobulin. In experimental oral inoculation, cats remain clinically normal yet develop a detectable IgG response in the CSF 4-12 weeks post inoculation and again 8-16 weeks after secondary exposure.64 Importantly, an IgG response in the CSF can occur after exposure to killed tachyzoites in previously infected cats.65 Therefore, observation of an IgG response in CSF does not necessarily document infection.65

Experimental inoculation does not result in an IgM response in the CSF.64 Potentially, therefore, detection of an IgM response in the CSF may be indicative of active disease, but this is yet to be confirmed.

**KEY POINTS: TOXOPLASMOSIS**

- **Neurological signs reflect a multifocal distribution in the CNS and include behavioral changes, seizures, ataxia, blindness, anisocoria, torticollis, vestibular disease, muscle hyperesthesia and paresis/paralysis.**
- **Diagnosis requires cautious interpretation of serum and CSF IgG/IgM titers and PCR identification.**
- **Clindamycin hydrochloride is the antibiotic of choice for the treatment of toxoplasmosis.**
The treatment of choice for cats with clinical toxoplasmosis is clindamycin hydrochloride at 12–25 mg/kg divided per day. Clindamycin is almost completely absorbed after oral administration and achieves high concentrations in most tissues, including the lung. Toxoplasma gondii can be identified in the aqueous humor of cats with uveitis using PCR; however, the organism can also be detected in the aqueous humor of clinically normal cats that have naturally been exposed to T gondii. Consequently, PCR detection of T gondii in aqueous humor does not provide definitive proof of active disease. A similar interpretation of PCR analysis of CSF is likely.

**Prognosis**

Unfortunately, the prognosis is poor for cats displaying neurological signs or severe respiratory disease as most will succumb to the disease. Despite this, cats with focal CNS toxoplasmosis may achieve long term remission.

**Hypertension**

Since the initial description of systemic hypertension in cats, the impact of hypertension systemically and on the nervous system has become increasingly recognized. A testament to this is a recent consensus statement from the American College of Veterinary Internal Medicine that has established guidelines for identification, evaluation and management of hypertension in dogs and cats. In healthy cats, normal systemic blood pressure, which is often reported as a systolic measurement, is 118–162 mmHg. The wide range in the reported normal values is likely to reflect a lack of standardization in technique and equipment used to measure blood pressure. Many factors affect blood pressure measurement including recording device, cuff size and operator skill, as well as patient factors such as size and demeanor of the cat. Although increasing age was found to be associated with increased blood pressure in one study, other reports have found no effect of age on blood pressure.

Hypertension has been defined as a sustained increase in systolic blood pressure ≥ 160–170 mmHg. Although the prevalence of hypertension in cats has not been accurately established, one study documented hypertension in 2% of healthy cats. In cats referred for evaluation of disease associated with hypertension, or animals with clinical signs compatible with hypertension, a 30% prevalence was found.

Hypertension can be divided into three categories: white coat, secondary and idiopathic.

- **White coat hypertension** is an artefactual increase in blood pressure that develops secondarily to excitement or anxiety, and is likely to be the result of activation of the sympathetic nervous system. It is observed in cats, and results in a median increase in systolic blood pressure of 17.6 mmHg ± 1.5 mmHg. While white coat hypertension does not cause a clinical problem, it does complicate definitive documentation of clinically relevant hypertension.

- **Secondary hypertension** develops as a consequence of systemic disease. By far the most common causes of secondary hypertension are renal disease (chronic renal disease and renal transplantation) and hyperthyroidism. Other causes include primary hyperaldosteronism, pheochromocytoma, diabetes mellitus and erythropoietin treatment.

- **Idiopathic hypertension** is defined as the presence of hypertension in the absence of other disease conditions that can lead to hypertension. It has also been referred to as primary or essential hypertension. Although hypertension in cats is most commonly classified as secondary, approximately 20% of cats with hypertension are considered idiopathic.
Pathology
Chronic systemic hypertension has a variety of pathological consequences that collectively are referred to as end-organ or target organ damage. Important target organ damage is observed in the kidneys, eyes, heart and nervous system. In the kidney, this leads to an accelerated decline in renal function, proteinuria and death. Hypertension can exist in animals at any stage of renal disease, and may be seen in non-azotemic animals. In the eye, hypertension leads to hypertensive retinopathy and choroidopathy (Fig 3). Exudative retinal detachment, retinal hemorrhage, multifocal retinal edema and tortuosity of the retinal vessels may be observed, and commonly result in blindness. In the heart, hypertension may result in cardiomegaly and left ventricular hypertrophy. A systolic murmur, gallop rhythm and congestive heart failure may be observed.

Clinical signs
Since hypertension in most cats can be categorized as secondary, clinical signs typically reflect the underlying disease process. Consequently, affected cats often demonstrate signs relating to renal disease or hyperthyroidism, given the high prevalence of hypertension with these disorders.

Pathophysiology
Although the pathophysiology underlying hypertensive encephalopathy remains unclear, it is thought to involve the development of vasogenic edema, which predominantly affects the white matter. With acute hypertension, the autoregulatory capacity of the brain vasculature may be exceeded, leading to hyperperfusion, breakdown of the blood–brain barrier, and cerebral edema. In experimental acute hypertension in cats, gross findings include coning of the vermis of the cerebellum, cerebellar herniation into the foramen magnum (Fig 4), rostral displacement of the colliculi, and widening and flattening of the cerebral gyri, all of which reflect raised intracranial pressure. Microscopically, the consequences of edema are observed such as marked pallor of the cerebral white matter, accentuation of the separation between axons and myelin sheaths, and widening of the perivascular space. In chronic hypertension, brain vasculature may be chronically vasoconstricted leading to hypertrophy and hyperplasia of the smooth muscle. As a result, fibrous changes develop, allowing leakage of plasma which ultimately causes degeneration of the vasculature predisposing to ruptures and microhemorrhages. Multifocal cerebral arteriosclerosis with hemorrhages has been observed in cats with spontaneous hypertension.

Diagnosis
A presumptive diagnosis of hypertensive encephalopathy is relatively straightforward and requires the documentation of hypertension (systolic blood pressure ≥ 160–170 mmHg) with contemporaneous neurological signs. The gold standard for blood pressure measurement is invasive intra-arterial monitoring. However, this is often not feasible in clinical practice. Consequently, indirect blood pressure monitoring is used most commonly. Accurate and reliable indirect blood pressure measurements can be performed using Doppler flow ultrasonography and oscillometry. Minimal, mild, moderate and severe risk categories for target organ damage have been defined based on blood pressure recordings (see below).

Interpretation of blood pressure recording

| Blood pressure (mmHg): | Risk of target organ damage |
|------------------------|-----------------------------|
| <150/95                | Minimal                     |
| 150–159/95–99          | Mild                        |
| 160–179/100–119        | Moderate                    |
| >180/120               | Severe                      |

Adapted from Brown et al (2007)
Identification of hypertension should prompt investigation for an underlying disease process. A complete blood count, biochemistry profile and urinalysis should be performed in all hypertensive cats. In cats older than 5 years of age, serum thyroxine level should also be measured. When indicated, endocrinological testing for Cushing’s disease or diabetes mellitus should be performed. In cats with suspected or confirmed renal disease, quantification of a proteinuria should be performed. Thoracic radiographs should be obtained to assess cardiovascular structures, and abdominal ultrasonography should be performed to assess renal structure and identify any concurrent disease. Echocardiography is warranted in cats with a murmur, gallop rhythm or other signs consistent with cardiac disease. In all cats with hypertension, echocardiography allows assessment of any secondary cardiac changes.

In cats with severe neurological dysfunction MRI may be warranted. In addition to assessing CNS pathology related to hypertension, MRI allows exclusion of other disease processes that can produce similar neurological signs. Given the potential for raised intracranial pressure and brain herniation in hypertensive encephalopathy, caution should be exercised prior to advanced imaging; the requirement for general anesthesia can lead to deterioration or death in animals with severe raised intracranial pressure. In humans with hypertensive encephalopathy, MRI of the brain discloses hyperintensities in the white matter of the parietal and occipital lobes of the cerebrum on T2-weighted images.96 Less frequently, similar findings may be observed in the brainstem.106 Magnetic resonance imaging in hypertensive cats has not been studied; however, given the gross and microscopic changes observed in affected cats, similar findings would be expected.

Prognosis
Unfortunately, control of hypertension does not appear to have a significant effect on survival time.82,83,108,109 However, amlodipine does seem to reduce the degree of proteinuria in cats with renal disease, and a reduction in proteinuria appears to have a positive effect on survival time.108,109
Hepatic encephalopathy

Hepatic encephalopathy is the clinical syndrome of abnormal neurological function caused by portosystemic shunting, with or without intrinsic liver disease. As a result, HE can develop in cats with acquired or congenital liver disorders. By far the most common cause of HE in cats is portosystemic shunting of blood secondary to a congenital vascular anomaly.

Clinical signs

Regardless of the cause of the underlying liver disease, the clinical signs of HE are similar and can be divided into systemic and neurological signs. Affected cats often display intermittent clinical signs that may be associated with eating. Cats with portosystemic shunts are generally small in stature, fail to thrive and grow, and lose weight. Pytalism is a common clinical sign, occurring in approximately 75% of cats. Other, less common clinical signs include gastrointestinal signs such as decreased appetite, anorexia, pica, vomiting, diarrhea or constipation. Cats may demonstrate polydipsia, and polyuria, pola- kiuia and stranguria may occur as a consequence of cystic calculi. Affected cats may have copper-coloured irises.

Pathophysiology

Although a complete understanding of the mechanisms underlying HE remains elusive, it is clear that the pathophysiology involved is multifactorial. Despite numerous potential factors, ammonia remains key in the development of HE. Ammonia is produced by bacteria in the gastrointestinal tract, primarily the colon, as a consequence of protein metabolism. It is also produced by the gastrointestinal cells as a result of metabolism of glutamine, the main cellular energy source for the epithelium. A further source of ammonia is the kidneys, during states of hypokalemia or alkalosis. Normally, the liver efficiently removes ammonia from the portal vasculature, ultimately converting it to urea. In animals with hepatic failure or portosystemic shunts, hyperammonemia may develop. However, the severity of the neurological signs does not always correlate with the degree of hyperammonemia. In fact, blood ammonia levels may be normal in cats with HE. This relates to a greater rate of uptake of ammonia in the CNS in HE, leading potentially to a high CNS ammonia level in the face of a normal blood ammonia level.

Although HE is a syndrome of neuronal dysfunction, the neuropathological consequences of increased CNS ammonia are played out in the astrocyte. Normally, CNS ammonia undergoes energy-dependent metabolism to glutamine by the astrocytes. With increased CNS ammonia, astrocytes become overwhelmed, leading to energy depletion. Additionally, the increased concentration of glutamine in astrocytes may act as an osmotic stress, leading to cell swelling. Increased numbers of swollen astrocytes—referred to as Alzheimer type II astrocytes—is the only structural change observed microscopically in the brain in HE. As a consequence of cellular edema, neurotransmitter processing in the astrocytes is affected, resulting in upregulation of neuronal benzodiazepine receptors and the production of neurosteroids which increase γ-aminobutyric acid (GABA) neurotransmission and thereby ultimately affect neuronal function. Ammonia may also have a direct toxic effect on neurons.

While ammonia remains a focal point in the pathogenesis of HE, other factors are also involved. Mercaptans are formed during the degradation of sulfur-containing amino acids. These substances exert a neurotoxic effect through inhibition of ATPase activity, thereby potentiating the effect of ammonia. Short and medium chain fatty acids are derived from bacterial metabolism of carbohydrates or from incomplete β-oxidation of long chain fatty acids in the liver. Like mercaptans, these molecules may inhibit energy metabolism as well as inhibiting urea cycle enzymes in the liver. A putative role for mercaptans, short and long chain fatty acids is unknown, but they may act synergistically with ammonia.

Hepatic encephalopathy may develop through an imbalance of inhibitory (GABA) and excitatory (glutamate) neurotransmitters. There is evidence to implicate exces-

By far the most common cause of hepatic encephalopathy in cats is portosystemic shunting of blood as the result of a congenital vascular anomaly. The severity of the neurological signs does not always correlate with the degree of hyperammonemia. In fact, blood ammonia levels may be normal in cats with HE.
Treatment of hepatic encephalopathy

Lactulose decreases the production/absorption of ammonia. This is accomplished in several ways: namely, by decreasing the colonic luminal pH, leading to conversion of ammonia (NH₃) to ammonium (NH₄⁺), trapping it intraluminally; decreasing transit time through the osmotic cathartic effect of lactulose; and interfering with intestinal absorption of glutamine, thereby decreasing the production of ammonia. Lactulose is a non-absorbable disaccharide that undergoes extensive metabolism by colonic bacteria, first to constituent monosaccharides and then to volatile fatty acids. Ultimately, lactulose decreases the production/absorption of ammonia. This is achieved in several ways: namely, by decreasing the colonic luminal pH, leading to conversion of ammonia (NH₃) to ammonium (NH₄⁺), trapping it intraluminally; decreasing transit time through the osmotic cathartic effect of lactulose; and interfering with intestinal absorption of glutamine, thereby decreasing the production of ammonia. Antibiotic therapy is often combined with lactulose administration. Antibiotics with activity against urease-producing bacteria are effective at reducing ammonia production. Neomycin is an oral aminoglycoside antibiotic that is effective at reducing urease-producing microbes, and is administered at 10 mg/kg PO q 12 h. Reduced hepatic metabolism in animals with liver disease may result in an increased incidence of neurotoxicity. Alternatively, ampicillin or amoxicillin-clavulanate can be administered. In severely affected animals, antibiotics (ampicillin, amoxicillin or metronidazole) should be administered parenterally.

There are several precipitating factors that can lead to HE, and these should be identified and corrected in the individual animal. Correction of dehydration, hypoglycemia and hypokalemia is imperative. Animals with clinical signs suggestive of gastrointestinal bleeding, such as melena, anorexia and vomiting, should be treated with H₂-blockers. In moderately to severely affected animals, food should be withheld until therapy results in significant improvements. Once a clinically significant improvement is obtained, affected animals should be fed a diet restricted in protein, with limited aromatic amino acids and short chain fatty acids. Commercial diets designed for animals with liver disease are available. Alternatively, diets designed for renal failure can be utilized in animals with HE.

Neurological signs reflect prosencephalic dysfunction and include abnormal mentation and seizures. Diagnosis relies on demonstrating abnormal liver function, compatible neurological signs, and response to therapy. Treatment is directed at reducing serum ammonia concentrations.

**KEY POINTS: HEPATIC ENCEPHALOPATHY**

- Neurological signs reflect prosencephalic dysfunction and include abnormal mentation and seizures.
- Diagnosis relies on demonstrating abnormal liver function, compatible neurological signs, and response to therapy.
- Treatment is directed at reducing serum ammonia concentrations.
