Assessment of Awareness Levels toward Colorectal Cancer Early Detection and Prevention in Saudi Arabia

Abstract

Background: Awareness of healthy individuals with colorectal cancer (CRC) can identify segments of the population that would most benefit from targeted education programs. Therefore, the aim of the present study was to assess the levels of awareness towards early colonoscopy screening and surgical management of colorectal cancer in the Kingdom of Saudi Arabia (KSA).

Methodology: This study randomly surveyed 1217 individuals, their age ranging from 20 to 70 years with a mean age of 36 years. An anonymous online questionnaire was used for data collection.

Results: The sample was consisted of 630/1217 (51.5%) women and 587/1217 (48.5%) men. Among the study population, 591/1217 (48.6%) think that people over the age of 50 years are more likely to develop colorectal cancer, 751/1217 (61.9%) think that the lack of exercise is a contributing factor for colorectal cancer, similarly 823/1217 (67.9%) think that the style of food and eating red meat can contribute to colorectal cancer. The majority of respondents affirm the benefits of CRC screening: 1067/1217 (88%) think that screening using endoscopy contributes to the early detection of colorectal cancer and 1075/1217 (88.8%) think that early endoscopy contributes to reduce the complications of colorectal cancer.

Conclusion: The awareness level of CRC among Western Province population of Saudi Arabia is relatively lower in some parts, and therefore, the implementation of awareness programs may improve the awareness of CRC.

Keywords: Colorectal cancer; Colonoscopy; Saudi Arabia; Early detection

Introduction

Colorectal cancer (CRC) is one of the commonest cancers with an estimated incidence of 72,090 males and 70,480 females and a cause of specific death of 51,370 in 2010 [1]. CRC is a multifactorial illness resulting from lifestyle, genetic, and environmental factors. There are hereditary and non-hereditary CRC types; though, the bulk is non-hereditary and mostly caused by somatic mutations in response to environmental factors. In previous years, scientists have concentrated their attention on the mechanisms behind these factors and the approaches of enhancing disease prevention and treatment. Enhancing the awareness of the population with respect to the advantages of a healthy lifestyle, comprising a balanced diet accompanying with exercise, could totally diminish CRC risk [2].

The choice to participate in CRC screening relies on a person’s awareness CRC screening. Awareness influenced assessments of cancer, attitudes towards CRC screening approaches, and motivation for screening. Factors mediating awareness counted in public education to target misconceptions, primary care physician efforts to endorse screening, and the inspiration of friends and family. Particular barriers to participation in populations with poorer participation rates included language barriers, logistical challenges to joining screening tests, and cultural beliefs [3].

The fecal occult blood test is widely used for CRC screening in several countries and its effectiveness in reducing CRC incidence and mortality has been demonstrated; however, the low participation rate in CRC screening programs is a problem to be solved in every country [4]. Improvement in the public awareness of CRC and promotion of CRC screening by physicians will help to raise the participation rate and reduce the number of deaths caused by CRC. Regarding screening colonoscopy, several studies have recently demonstrated its effectiveness in reducing CRC incidence and mortality. However, at present, CRC screening colonoscopy is not adopted as a primary population-based screening tool because of staffing constraints in relation to large population sizes, increased medical costs [5].

CRC is one of the commonest cancers and a prime cause of cancer mortality in the Kingdom of Saudi Arabia (KSA). CRC in KSA is often diagnosed at progressive stages with metastases and is linked to poor prognosis and short survival. Countrywide awareness campaigns and screening programs for CRC are essential for prevention, early detection and sufficient management of CRC [6]. Therefore, the aim of the present study was to assess the levels of awareness towards toward early colonoscopy screening and surgical management of colorectal cancer in Saudi Arabia.
Materials and Methods

This is a community survey involved 1217 volunteers living in the city of Jeddah, Kingdom of Saudi Arabia (KSA). All study subjects were randomly selected regardless to gender or sex. A self-administered online questionnaire was used for data collection including: Demographic characteristics (age, gender, education level, and income). Opinions about Colorectal cancer (CRC) assessment including 7 questions. A score of 1 was given to yes and 0 otherwise. For each subject, a maximum score of 7 was calculated. A scoring system was applied to measure the respondents’ beliefs towards CRC. The knowledge score was categorized into two levels indicated by poor knowledge (0-2), average knowledge (3-4) and good knowledge (5-7). Knowledge about early endoscopy assessment including 3 questions. A score of 1 was given to yes and 0 otherwise. For each subject, a maximum score of 3 was calculated. A scoring system was applied to measure the respondents’ knowledge about early endoscopy. The knowledge score was categorized into 2 levels indicated by weak knowledge (0-1) and good knowledge (2-3).

a. Ethical consent: An informed consent was obtained from the participants included in this research before filling the questionnaire.

b. Statistical analysis: Data were entered into the Statistical Package for Social Sciences (SPSS, version 20) and descriptive analysis conducted. Association of respondents’ characteristics with beliefs about CRC and knowledge about early endoscopy as a prevention tool was evaluated using: Frequencies and percentages, Chi-squared test. Statistical significance was accepted at p < 0.05.

Results

In this study awareness toward CRC was assessed among 1217 Saudi, their ages ranging from 18 to 70 with mean age of 36 years. The response rate was 96.3%. Out of 1217 participants, 630/1217 (51.8%) were males and 587/1217 (48.2%) were females (Figure 1).

The results show that the majority of respondents (48.6%) think that people over the age of 50 years are more likely to develop colorectal cancer, followed by 36.2% of the respondents who seemed to be not sure if people over the age of 50 years are more likely to develop colorectal cancer or not. Then 15.2% of the respondents think not that people over the age of 50 years are more likely to develop colorectal cancer, as indicated in Table 1 & Figure 2. It shows that there are statistically significant differences in the responses of respondents to the section on “Do you think that age is one of the factors of colorectal cancer” attributed to the age (F = 6.671, p value=0.001 <0.05). The null hypothesis (equality of the mean of age within each of the 3 groups) is clearly rejected (p = 0.001).

The results show that the majority of respondents (61.9%) think that the lack of exercise of the contributing factors of colorectal cancer, followed by 22.9% of the respondents who seemed to be not sure if the lack of exercise of the contributing factors of colorectal cancer. Then 15.2% of the respondents think not that the lack of exercise of the contributing factors of colorectal cancer, as indicated in Table 1 & Figure 2.
Table 1: Responses to questions on knowledge regarding colorectal cancer.

| Questions                                                                 | No   | Yes  | Don't Know |
|---------------------------------------------------------------------------|------|------|------------|
| Q1: Do you think that age is one of the factors of colorectal cancer      | 398  | 467  | 348        |
| Q2: People over the age of 50 years are more likely to develop colorectal cancer | 185  | 591  | 440        |
| Q3: Do you think the lack of exercise of the contributing factors of colorectal cancer | 185  | 751  | 278        |
| Q4: Do you think the style of food and eating red meat can contribute to colorectal cancer factors | 134  | 823  | 255        |
| Q5: Do you think that genetics play a role in colorectal cancer           | 295  | 634  | 284        |
| Q6: Do you think that smoking is one of colorectal cancer factors         | 166  | 793  | 253        |
| Q7: Do you think that there are diseases may cause or lead to colorectal cancer | 93   | 735  | 382        |
| Q8: Do you think that screening using endoscopy contribute to the early detection of colorectal cancer | 13   | 1067 | 133 (11%)  |
| Q9: Do you think it must be an annual survey checks for people above 50 years | 93   | 948  | 175        |
| Q10: Do you think that early endoscopy contributes to reduce the complications of colorectal cancer | 24   | 1075 | 111        |

The results show that the majority of respondents (67.9%) think that the style of food and eating red meat can contribute to colorectal cancer factors, followed by 21.0% of the respondents who seemed to be not sure if the style of food and eating red meat can contribute to colorectal cancer factors or not. Then 11.1% of the respondents think not that the style of food and eating red meat can contribute to colorectal cancer factors, as indicated in Table 1 & Figure 2.

The results show that the majority of respondents (52.3%) think that genetics play a role in colorectal cancer, followed by 24.3% of the respondents who think not that genetics play a role in colorectal cancer or not. Then 23.4% of the respondents seemed to be not sure if genetics play a role in colorectal cancer or not, as indicated in Table 1 & Figure 2. It shows that there are statistically significant differences in the responses of respondents to the section on “Do you think that genetics play a role in colorectal cancer” attributed to the age (F = 6.507, p value=0.002 <0.05).

The results show that the majority of respondents (65.4%) think that smoking is one of colorectal cancer factors, followed by 20.9% of the respondents who seemed to be not sure if smoking is one of colorectal cancer factors. Then 13.7% of the respondents think not that smoking is one of colorectal cancer factors, as indicated in Table 1 & Figure 2.

The results show that the majority of respondents (60.7%) think that mental illnesses like thinking and anxiety lead to obesity, which may increase the risk of CRC, followed by 31.6% of the respondents who seemed to be not sure if mental illnesses like thinking and anxiety lead to obesity. Then 7.7% of the respondents think not that mental illnesses like thinking and anxiety lead to obesity, as indicated in Table 1 & Figure 2. It shows that there are statistically significant differences in the responses of respondents to the section on “Do you think that there are diseases may cause or lead to colorectal cancer attributed to the age (F = 8.129, p value=0.000 <0.05). The null hypothesis (equality of the mean of age within each of the 3 groups) is clearly rejected (p = 0.000).

The results show that the majority of respondents (88.0%) think that screening using endoscopy contribute to the early detection of colorectal cancer, followed by 11.0% of the respondents who seemed to be not sure if screening using endoscopy contribute to the early detection of colorectal cancer or not. Then 1.1% of the respondents think not that screening using endoscopy contribute to the early detection of colorectal cancer, as indicated in Table 1 & Figure 2.

The results show that the majority of respondents (78.0%) think that it must be an annual survey checks for people above 50 years, followed by 14.4% of the respondents who seemed to be not sure if it must be an annual survey checks for people above 50 years or not. Then 7.6% of the respondents think not that it must be an annual survey checks for people above 50 years, as indicated in Table 1 & Figure 2. The results show that the majority of respondents (88.8%) think that early endoscopy contributes to reduce the complications of colorectal cancer, followed by 9.2% of the respondents who seemed to be not sure if early endoscopy contributes to reduce the complications of colorectal cancer or not. Then 2.0% of the respondents think not that early endoscopy contributes to reduce the complications of colorectal cancer, as indicated in Table 1 & Figure 2.

On asking them about the treatment of colorectal cancer the majority of respondents (72.5%) think that the treatment for colorectal cancer is surgical, followed by 16.2% of the respondents who think that the treatment for colorectal cancer is chemotherapy. Then 11.3% of the respondents think that the
treatment for colorectal cancer is radiotherapy, as indicated in Figure 3. It shows that there are no statistically significant differences in the responses of respondents to the section on "In your opinion what is the treatment for colorectal cancer attributed to the age \((F = 2.444, p \text{ value}=0.087 >0.05)\). On asking them, what are the survival ratio for after 5 years of the early diagnosis of colorectal cancer, the majority of respondents (49.5%) do not know what are the survival ratio for after 5 years of the early diagnosis of colorectal cancer, followed by 21.7% of the respondents who think that the survival ratio for after 5 years of the early diagnosis of colorectal cancer is 90%. Then 17.4% of the respondents think that the survival ratio for after 5 years of the early diagnosis of colorectal cancer is 70%, and 8.6% of the respondents who think that the survival ratio for after 5 years of the early diagnosis of colorectal cancer is 40%. Finally 2.8% of the respondents think that the survival ratio for after 5 years of the early diagnosis of colorectal cancer is 20%, as shown in Figure 4.

**Figure 3:** Describe the opinion on what is the treatment for colorectal cancer.

**Figure 4:** Describe the opinion on what are the survival ratio for after 5 years of the early diagnosis of colorectal cancer?

### Discussion

Early detection of cancer significantly raises the likelihoods for successful overall management of patients. The most important components of early detection of CRC are education to encourage early diagnosis and screening. Improved awareness of potential threatening signs of CRC, amongst physicians, nurses and other health care providers as well as among the general public, can have a great influence on the CRC control.

In the present study we tried to assess the general Saudi population awareness toward CRC. With regard to the question “Do you think that age is one of the factors of colorectal cancer”, only 38.5% think that age is risk factor for CRC. These findings indicate a poor awareness level, since the relationship between age and CRC was well established in several studies [7-9]. Increasing the cutoff screening age reduces the numbers of patients who undergo colonoscopy evaluation in CRC screening programs [10]. When specified the age to over 50 years in the present about 48.6% thought that people over the age of 50 years are more likely to develop colorectal cancer. However, around 78% thought that it must be an annual survey checks for people above 50 years.

In the present study about 61.9% of the participants thought that the lack of physical activities is a risk factor for colorectal cancer. This percentage is relatively not so high. Physical activities have been found to reduce the risk of CRC. The reverse relationship between physical activities and CRC is constant [11]. The rate, duration and intensity of physical activities are essential components of a public health message to reduce risk of CRC via practicing of physical activity. On the other hand, difficulties in assessing the precise amount of physical activity required and frequency and intensity of activity result in only rough approximations of dose wanted for a protective influence. Considerable amount of the literature propose that more intense activity is required to reduce CRC risk and that wherever between 3.5 and 4 hours of vigorous physical activities per week may be necessary to improve protection. Numerous biological processes have been suggested to clarify the relationship between physical activities and CRC; several of these processes also support the opinion that intense activities are most protective. Biological mechanisms such as: physical activities increasing gut motility; improving the immune system; reducing insulin and insulin-like growth factor levels; reducing obesity; increasing free radical scavenger systems; and influencing prostaglandin levels. Approximately 12-14% of CRC could be attributed to lack of frequent contribution in vigorous physical activity [12].

About 67.9% of the participants thought that the style of food and eating red meat can contribute to CRC risk. However, this is relatively higher percentage indicating some sorts of awareness among the study population. Meat has been categorized by International Agency for Research on Cancer (IARC) as carcinogenic to humans. Numerous mechanisms for mutagenic properties of meat eating have been recognized but it is not clear, which cause cancer in humans. The scope to which whole abstention from meat protects against cancer is also unclear [13]. A recent investigation by the World Health Organisation (WHO) has found that the consumption of processed meat and potentially red meat promotes carcinogenesis and can increase the risk of colorectal cancer. Processed meat is more carcinogenic compared to red meat because of the abundance of potent nitrosyl-heme molecules that form N-nitroso compound [14].

Approximately 52.3%, thought that genetic risk factors play a role in CRC. It was found that about 3-5% of CRCS
are due to inherited genetic mutations [15]. Genome-wide association studies have identified 17 germline single nucleotide polymorphisms (SNPs) significantly associated with incident CRC [16].

A round 65.4% thought that smoking is one of colorectal cancer factors. Smoking has been implicated in many malignant diseases, but its association with colorectal cancer (CRC) is controversial. Some studies have shown that smoking was associated with a significantly increased risk of CRC. The associated risk was higher for men and for rectal cancers. The association of tobacco consumption and CRC risk appeared to be dose-related [17].

About 60.7% of the participants thought that mental illnesses like thinking and anxiety lead to obesity, which may increase the risk of CRC. The causal relationship from obesity to anxiety disorders and vice versa is still under investigation. Pharmacological factors used for obesity treatment, such as rimonabant, were associated with depression and anxiety. Questions still remain regarding the role of obesity severity and subtypes of anxiety disorders. Besides, it is well known that in the morbidly obese patients before undergoing surgical treatment, unusual prevalence of psychopathology, namely depression and anxiety disorders, is observed [18].

There is strong evidence that modifiable lifestyle factors such as obesity play a key role in colorectal carcinogenesis. Epidemiologic data have consistently reported a positive association between obesity and colorectal cancer. The relative risk associated with general obesity (as assessed by BMI) is higher in men than in women and for cancer of the colon than for cancer of the rectum. Abdominal obesity (as assessed by waist circumference or waist-to-hip ratio) is associated with an increased risk of colorectal cancer in both sexes, with stronger associations for cancer of the colon than for cancer of the rectum [19]. Plausible biological mechanisms include insulin resistance, hyperinsulinemia, chronic inflammation, altered levels of growth factors, adipokines, and steroid hormones. In addition to its effect on colorectal cancer incidence, obesity may play a role in colorectal cancer recurrence, treatment outcomes, and survival [20,21]. The adipokines adiponectin and leptin and adipocyte-mediated chronic low-grade inflammation represented by the acute-phase C-reactive protein may explain a substantial part of the association between obesity and risk of colorectal cancer [22].

A bout 88.0% of the study subjects believe that screening using endoscopy contribute to the early detection of colorectal cancer. High-quality colonoscopy is needed to reduce the morbidity and mortality of colorectal cancer. Full-spectrum colonoscopy has recently shown potential in improving adenoma detection during colonoscopy [23]. Miss rate of polyps has been shown to be substantially lower with full-spectrum endoscopy (FUSE) compared with standard forward-viewing (SFV) colonoscopy in a tandem study at per polyp analysis. However, there is uncertainty on whether FUSE is also associated with a higher detection rate of colorectal neoplasia, especially advanced lesions, in per patient analysis [24]. However, about 88.8% thought that early endoscopy contributes to the reduction of the complications of colorectal cancer.

Several studies have conducted in this context from Saudi Arabia. A recent study to explore the knowledge and awareness about colorectal cancer (CRC) among undergraduate students of one of the leading universities in Saudi Arabia, along with the mode of information access. The study concluded that knowledge and awareness of students about CRC were not up to the mark. Medical students and female students had better knowledge in a few areas, but the overall situation is dismal [25]. Another study investigated colorectal cancer (CRC) awareness in healthy individuals in Saudi Arabia in order to identify segments of the population that would most benefit from targeted education programs. The study concluded that although older individuals and those with higher education tended to answer questions correctly more often, there were some misconceptions regarding universally accepted screening protocols, symptoms, and general understanding of CRC in Saudi Arabia. A national education/screening program in Saudi Arabia is recommended to improve CRC knowledge [26].

Furthermore, several similar surveys have been conducted in Saudi Arabia. In a survey included 1070 participants most respondents believe that screening for colon cancer should begin at symptom onset (42.9%). Less than 20% of all respondents believe that polyps are a risk factor for CRC, which varied significantly according to level of education; however, even the most educated answered correctly less than 50% of the time. Similarly, only 34.8% of all respondents knew that a family history of CRC imparted a personal risk for CRC [27]. In another study included 371 participants, of whom 52%, 86% and 60%, didn’t hear about early screening of CRC didn’t perform screened of CRC and didn’t know where to screen for colorectal cancer, respectively. The subjective assessment of the participants’ Level of knowledge about colorectal cancer revealed poor, good and excellent in 53%, 37% and 10% of the respondents, respectively. Highest percentage for education level about Public awareness for CRC universal by 45% and lowest unlettered by 4% which varied significantly according to level of education. About 6 from 11 diagnosed with CRC and have a family history of CRC [28].

Although, the questionnaire used in the present study was comprehensive regarding with regard to awareness associated factors, but many variables might be answered subjectively, due some community barriers.

Conclusion

The awareness level of CRC among Western Province is relatively lower in some parts, and therefore, the implementation of awareness programs may improve the awareness of CRC through continuous education programs, local media, or campaigns to encourage the early detection CRC.
