**Abstract.** Background/Aim: New therapeutic agents and prognostic biomarkers for gastric cancer are needed. We analyzed the composition of peripheral blood T-cell subpopulations in response to chemotherapy in patients with gastric cancer. Patients and Methods: Peripheral blood samples were collected from patients diagnosed with gastric cancer before and after chemotherapy (FOLFOX: oxaliplatin, 5-fluorouracil, and leucovorin). Peripheral blood mononuclear cells were isolated. Patients were divided into responder (n=5) and non-responder groups (n=2) based on their chemotherapy outcomes. Results: Non-responders showed lower numbers of CD4+/total cells and CD8+/total cells after chemotherapy compared to the responder group, but the difference was not significant (p=0.905, p=0.095). Naïve T, central memory T, effector memory T and effector T-cell counts differed in both groups after chemotherapy. Conclusion: Changes in peripheral T-cell subpopulations after chemotherapy were confirmed in patients with gastric cancer, which may be a prognostic predictor and development of therapeutic agents.

Gastric cancer is the fifth most frequently diagnosed cancer and third most frequent cause of cancer-related death worldwide (1). Early-stage gastric cancer has a high 5-year survival rate of more than 90%; however, lymph node metastasis and disease recurrence are common in the advanced stage after treatment, resulting in poor prognosis (2). Various therapies such as radiation therapy or adjuvant chemotherapy have been administered to patients with gastric cancer after surgery to improve prognosis. However, these therapies do not reduce recurrence or increase the survival rate of patients; therefore, they are no longer recommended for improving prognosis in patients with gastric cancer (3, 4). Palliative chemotherapy is administered to patients when surgery is impossible and the treatment outcome is non-significant because of distant metastasis and poor prognosis (5, 6).

Programmed death-ligand 1 (PD-L1) is a protein present on the surface of cancer cells or hematopoietic cells, whereas programmed cell death protein 1 (PD1) is a protein present on the surface of T-cells. When PD-L1 binds to PD1, T-cells cannot attack cancer cells (7). Recently, anti-PD1 and anti-PD-L1 agents that prevent the binding of these two proteins have replaced conventional cytotoxic agents (8, 9). Immunotherapy has almost doubled the overall median survival rates of patients with melanoma and non-small cell lung cancer, and is being used for other cancer types (10, 11). Biomarkers play an important role in objectively measuring and evaluating the response of drugs to normal biological processes, disease progression, and treatment methods, and have clinical value when they can be easily identified such as in peripheral blood samples (12). In patients with cancer, understanding the difference between responders and non-responders to specific drugs or monitoring treatment effects...
response or safety aspects were considered while adjusting the dose and interval of the anticancer drug. Peripheral blood was collected and leucovorin and was administered at intervals of 2 weeks. Tumor chemotherapy and response assessment.

Other than the initial assessment, investigation of the complete blood cell count with differential and measures of the primary tumor size were performed. A reduction in the primary tumor size was defined as a partial response (PR). A minor response or no change after chemotherapy was considered as stable disease (SD). New lesions or a greater than 25% increase in primary tumor size were considered as progressive disease (PD).

Therefore, this study was conducted to analyze the characteristics of the peripheral blood T-cell subpopulation in patients with gastric cancer before and after chemotherapy to determine the association between the composition of peripheral T-cell subpopulations and gastric cancer prognosis. We investigated the use of the peripheral blood T-cell subpopulation as a biomarker for gastric cancer prognosis and possibility of using immunotherapy for treating this cancer.

**Patients and Methods**

**Study design and patient selection.** Patients over 18 years of age who were histologically diagnosed with gastric cancer at the Chungnam National University Hospital (Daejeon, Republic of Korea) between September 2019 and March 2020 and who had a World Health Organization performance status of 0 or 1 were enrolled. Those with a history of previous chemotherapy, secondary malignancy, and inadequate renal function (serum creatinine clearance ≤60 ml/min) were excluded. Pre-treatment clinical evaluation included determination of the complete blood cell count with differential and serum multichannel chemical analysis. For clinical staging, upper gastrointestinal endoscopy with biopsy, abdominal computed tomography, and chest radiography were performed. This study was approved by the institutional review board of the Chungnam National University Hospital (2019-09-047).

**Chemotherapy and response assessment.** The chemotherapy regimen for all patients was the same (FOLFOX; oxaliplatin, 5-fluorouracil, and leucovorin) and was administered at intervals of 2 weeks. Tumor response or safety aspects were considered while adjusting the dose and interval of the anticancer drug. Peripheral blood was collected from all patients and analyzed before and after 3 cycles of chemotherapy. Before each cycle, complete blood count and levels of electrolyte and serum creatinine were analyzed, and a liver function test was performed. A reduction in the primary tumor size was measured as a response to chemotherapy by endoscopy and abdominal computed tomography (CT). Complete disappearance of lesions after endoscopy and CT was considered as a clinically complete response (CR). A tumor size reduction greater than 50% compared with the initial tumor size was defined as a partial response (PR). A minor response or no change after chemotherapy was considered as stable disease (SD). New lesions or a greater than 25% increase in primary tumor size were considered as progressive disease (PD).

Therefore, this study was conducted to analyze the characteristics of the peripheral blood T-cell subpopulation in patients with gastric cancer before and after chemotherapy to determine the association between the composition of peripheral T-cell subpopulations and gastric cancer prognosis. We investigated the use of the peripheral blood T-cell subpopulation as a biomarker for gastric cancer prognosis and possibility of using immunotherapy for treating this cancer.

**Flow cytometry and intracellular cytokine staining.** The following human antibodies were used: anti-PD-1 (FITC), anti-CD4 (PerCP-Cy5.5), anti-CD127 (APC), anti-CD8 (AF700), and anti-CCR7 (BV786) from BioLegend (San Diego, CA, USA). Anti-CD45RA (PE-Cy7), anti-CD3 (APC-Cy7), and anti-CD25 (BV421) were purchased from BD Biosciences (San Jose, CA, USA). To exclude dead cells from the analysis, the viability dye LIVE/DEAD® Fixable Aqua (Thermo Fisher Scientific, Waltham, MA, USA) was used as a live/dead marker. For intracellular staining of forkhead box protein P3, the cells were fixed and permeabilized using the Foxp3/Transcription factor staining buffer set (eBioscience, San Diego, CA, USA) and incubated with an antibody against the T-reg transcription factor marker for 30 min at 4°C. After washing, the stained cells were analyzed using BD LSR Fortessa X-20 (BD Biosciences) and FlowJo software (TreeStar, Ashland, OR, USA).

**Preparation of cryopreserved human peripheral blood mononuclear cells (PBMCs).** PBMCs were separated from peripheral blood using lymphocyte separation medium (Corning, Inc., Corning, NY, USA) and by gradient centrifugation, and all samples were cryopreserved in Mr. Frosty™ Freezing Container (Thermo Fisher Scientific) at −80°C. The samples were then transferred to liquid nitrogen until further use. Cryopreserved PBMCs were rapidly thawed and rested in Roswell Park Memorial Institute 1640 medium supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin (all from Corning, Inc.) and incubated for 15 h at 37°C in a humidified atmosphere with 5% CO₂.

**Statistical analysis.** Changes in PBMCs of each patient before and after chemotherapy were analyzed using the Mann-Whitney U and
Figure 1. Continued
Wilcoxon tests. All analyses were performed using SPSS software (version 19.0, SPSS, Inc., Chicago, IL, USA). *p*-Values were determined using two-sided tests and values <0.05 were considered as significant.

**Results**

**Patient characteristics.** Seven patients who were diagnosed with gastric cancer and progressed to response evaluation after 3 cycles of chemotherapy were enrolled in the study; the clinical characteristics of these patients are summarized in Table I. The results of response evaluation showed that two patients were non-responders and five were responders (CR: 0, PR: 1, SD: 4, and PD: 2). Among all patients, 86% (n=6) were male and their mean age was 64.42 (9.48) years. All patients were in stage IV, and the initial chemotherapy regimen was the same as FOLFOX.

**Peripheral T-cell subpopulations.** The gating strategy used to define T-cell subpopulations in PBMCs is summarized in (Figure 1A). CD4+/total cell (%), CD8+/total cell (%), CD4+ (%), CD8+ (%), CD4+PD-1 (%), and CD8+PD-1 (%) of patients in both the groups were compared (Figure 1B). In the non-responder group, the number of CD4+/total cells (%) and CD8+/total cells (%) decreased after chemotherapy compared to in the responder group but the difference was not significant (*p*=0.905 and *p*=0.095). However, CD4+ (%), CD8+ (%), CD4+PD-1 (%), and CD8+PD-1 (%) showed no difference before and after treatment in both groups.

**Composition of T-Cell subsets change after chemotherapy.** Compositional changes in naïve T-cells (TN), central memory T-cells (TCM), effector memory T-cells (TEM), and effector T-cells (TEFF) before and after chemotherapy in both groups were compared (Figure 2A). The number of CD4+ and CD8+ T-cell subsets after chemotherapy in the two groups differed, but the difference was not significant. Each T-cell subset was further categorized as TN/CD4+, TN/CD8+; TCM/CD4+, TCM/CD8+; TEM/CD4+, TEM/CD8+, and TEFF/CD4+ and TEFF/CD8+ groups to analyze the changes after chemotherapy (Figure 2B). However, the differences between the number of subsets in both the groups were not significant.

**TCM/TEFF ratio differed between groups after chemotherapy.** In both groups, the CD4+ TCM/TEFF ratio was similar before and after chemotherapy, whereas the CD8+ TCM/TEFF ratio decreased after chemotherapy.
(Figure 3); however, the differences were not significant ($p=0.109$ and $p=0.156$). The CD4+ TCM/TEFF and CD8+ TCM/TEFF ratios in both groups differed after chemotherapy but the differences were not significant ($p=0.437$ and $p=0.062$).

**Changes in regulatory T-cell chemotherapy.** To determine the role of regulatory T-cells (T-reg), changes in the number of PD1+/Fr. I, PD1+/Fr. Lli, and PD1+/Fr. Ill (%) in both groups were analyzed after chemotherapy (Figure 4A). In the responder group, the number of PD1+/Fr. I, PD1+/Fr. Lli, and PD1+/Fr. Ill (%) did not change after chemotherapy, whereas in the non-responder group, the number of PD1+/Fr. I and PD1+/Fr. II (%) decreased after chemotherapy but the difference was not significant ($p=0.238$ and $p=0.095$). No significant difference was observed between the number of Fr. I/CD25+/CD127-/ or...
Discussion

In this study, we compared the compositional changes in peripheral T-cell subpopulations in responder and non-responder groups of patients with gastric cancer. We observed compositional changes in the peripheral T-cell subpopulations; however, as the number of enrolled patients in this study was small, significance could not be determined. However, to the best of our knowledge, this is the first study to analyze the compositional changes in peripheral T-cell subpopulations in patients with gastric cancer and clinical outcomes after chemotherapy. New treatment agents are required to treat gastric cancer, as the efficacy of existing cytotoxic agents is low (17, 18). The failure to maintain homeostasis between immune activation and immune suppression plays an important role in cancer development (19). The immune system can act to either induce or prevent cancer, but the role of T-cells is also important (20), as CD8+ T-cells remove tumor cells during cancer development (21, 22). Previous studies showed that the population of CD8+ T-cells is significantly reduced in patients with head and neck cancer (23). Changes in the composition of T-cell subpopulations are associated with cancer incidence; however, in this study, we found that changes in the composition of CD4+ cells and CD8+ cells were associated with the prognosis of gastric cancer, although the difference was not significant. In a normal host, T-cell memory lasts for a lifetime because some memory T-cells self-renew following exposure to the same antigen (24). CD4+ and CD8+ TEM produce effector cytokines, express perforin, and exert cytolytic activity. The self-renewing state required to be maintained by these signals requires a microenvironment of lymphoid organs (25). When antigens are removed, most effector cells are eliminated, whereas the self-renewing population is retained (26). CD4+ and CD8+ memory T-cells are correlated with the clinical response in melanoma patients treated with ipilimumab (27).

In this study, changes in TN, TCN, TEM, and TEFF after initial chemotherapy were analyzed, and alterations in their composition before and after chemotherapy were observed in both groups. In 22 patients with non-small cell lung cancer treated with nivolumab, progression-free survival was significantly high with a high TCM/TEFF ratio (median survival: 91 vs. 215 days) (28). In the present study, CD4+ TCM/TEFF and CD8+ TCM/TEFF ratios did not significantly differ between groups after chemotherapy. Changes in the T-cell composition are considered to be related to the prognosis of gastric cancer, and further studies are required to confirm this hypothesis.
T-regs are characterized by co-expression of CD4 and CD25, and their numbers are increased in lung, breast, and ovarian cancers (29, 30). T-regs can be classified as Fr. l, Fr. ll, and Fr. depending on the expression of CD4 and CD25 (31). To confirm the changes in the number of T-regs, Fr. l, Fr. ll, and Fr. Lll were compared between groups before and after chemotherapy. In the non-responder group, PD1+/Fr. L and PD1+/Fr. ll (%) were decreased after chemotherapy ($p=0.238$, $p=0.095$). Because the number of patients analyzed was small, significant results were not observed.

Changes in peripheral T-cell subpopulations were identified in patients with gastric cancer, and analysis was performed by considering chemotherapy as an important aspect. One limitation of this study is that the results are difficult to generalize because of the small sample size of patients and the mechanism involved in changes in T-cell subpopulations was not determined.

In conclusion, the composition of peripheral T-cell subpopulations was changed in patients with gastric cancer after chemotherapy. Although there was no statistical significance due to the small number of enrolled patients, it is meaningful that changes in T-cell subpopulations were confirmed. Therefore, the possibility of an association between the composition of peripheral T-cell subpopulations and gastric cancer prognosis is actual. Peripheral T-cell subpopulations may be useful as biomarkers for gastric cancer prognosis and development of therapeutic agents. However, further research on this is still needed.
