The Jacobi MIMO Channel
Ronen Dar, Meir Feder, Fellow, IEEE, and Mark Shtaif

Abstract—This paper presents a new fading model for multi-input multi-output channels: the Jacobi fading model. It asserts that $\mathbf{H}$, the transfer matrix which couples the $m_i$ inputs into $m_o$ outputs, is a submatrix of an $m_r \times m_r$ random (Haar-distributed) unitary matrix. The (squared) singular values of $\mathbf{H}$ follow the law of the classical Jacobi ensemble of random matrices, hence the name of the channel. One motivation to define such a channel comes from multimode/multicore optical fiber communication. It turns out that this model can be qualitatively different from the Rayleigh model, leading to interesting practical and theoretical results. This paper first evaluates the ergodic capacity of the channel. Then, it considers the nonergodic case, where it analyzes the outage probability and the diversity-multiplexing tradeoff. In the case where $k = m_i + m_o - m > 0$, it is shown that at least $k$ degrees of freedom are guaranteed not to fade for any channel realization, enabling a zero-outage probability or infinite diversity order at the corresponding rates. A simple scheme utilizing (a possibly outdated) channel state feedback is provided, attaining the no-outage guarantee. Finally, noting that as $m$ increases, the Jacobi model approaches the Rayleigh model, the paper discusses the applicability of the model in other communication scenarios.

I. INTRODUCTION

In multi-input multi-output (MIMO) channels, a vector $\mathbf{x}$ of $m_i$ signals is transmitted, a vector $\mathbf{y}$ of $m_o$ signals is received, and an $m_r \times m_r$ random matrix $\mathbf{H}$ represents the coupling of the input into the output so that the received vector is $\mathbf{y} = \mathbf{Hx} + \mathbf{z}$, where $\mathbf{z}$ is a noise vector. In this paper, we consider a channel matrix $\mathbf{H}$ which is a submatrix of a Haar-distributed unitary matrix, i.e., drawn uniformly from the ensemble of all $m_r \times m_r$ unitary matrices, $m \geq m_r$. The three classical and most well-studied random matrix ensembles are the Gaussian, Wishart, and Jacobi (also known as MANOVA) ensembles [1]–[4]. A common model for the channel matrix $\mathbf{H}$ in fading wireless communication is a matrix with independent Gaussian elements (also known as the Rayleigh model). In that case, $\mathbf{HH}^\dagger$ is a Wishart matrix. For the model assumed in this paper, $\mathbf{H}^\dagger \mathbf{H}$ follows the Jacobi ensemble. It turns out that this model is both practically useful and qualitatively different from other fading models such as the Rayleigh [5]–[7], Rician [8]–[10], and Nakagami [10]–[13].

Jacobi ensembles, forming an important part of classical random matrix ensembles, are of considerable interest in connection with multivariate statistics and random matrix theory [1]–[3]. These ensembles have been successfully applied in several problems. One notable example is related to quantum conductance/transmission in mesoscopic systems [4], [14]–[18], where scattering is modeled by a random unitary matrix (owing to flux conservation) and the blocks of unitary matrix are then the transmission/reflection matrices which govern the conductance/transmission properties. This paper provides another application in communication theory.

The motivation to introduce the Jacobi channel comes from recent developments in optical fiber communication. The expected capacity crunch in long-haul optical fibers [19], [20] led to proposals for “space-division multiplexing” (SDM) [21], [22], that is to have several links at the same fiber, by either multiple single-mode fiber strands within a fiber cable, multiple cores within a multicore fiber, or multiple modes within a multimode waveguide. An SDM system with $m_r$ parallel transmission paths per wavelength can potentially multiply the throughput of a certain link by a factor of $m$. Since $m$ can potentially be chosen very large, SDM technology is highly scalable. Now, a significant crosstalk between the optical paths raises the need for MIMO signal processing techniques. Unfortunately, for large size MIMO (large $m$), this is unfeasible currently in the optical rates. Assuming that faster computation will be available in the future and having in mind that replacing optical fibers to support SDM is a long and expensive procedure, a long-term design is sought after. To that end and more, it was proposed to design an optical system that can support relatively large number of paths for future use, but at start to address only some of the paths. In this scenario, the channel can be modeled as a submatrix of a larger unitary matrix, i.e., the Jacobi model is applicable.

This under-addressed channel is discussed in [23] where simulations of the capacities and outage probabilities were presented. In this paper, we further analyze the channel in the ergodic and nonergodic settings, where we provide analytical expression for the capacity, outage probability, and the diversity-multiplexing tradeoff (DMT). It should be noted that in optical systems, the outage probability is an important measure, required to be very low. Evidently, since the entire channel matrix is unitary, when all paths are addressed, a zero-outage probability can be attained for any transmission rate. An interesting result that comes out of this work is that there are situations where a partial number of paths are addressed yet a number of streams are guaranteed to experience zero outage. Thus, choosing the number of addressed paths and the
corresponding rate is a very critical design element that highly reflects on the system outage and performance. A preliminary description of our work, in the context of the SDM optical channel, is provided in [24].

A possibly practical outcome of this work is a simple communication scheme, with channel state feedback, that achieves the highest rate possible with no outage. The scheme works even when the feedback is “outdated,” and it allows simple decoding with no complicated MIMO signal processing, making it plausible for optical communication. We note that while our theoretical findings indicate that the no-outage promise can be attained with no feedback, the quest for such simple schemes is open.

As noted above, the motivation for this work comes from optical fiber communication. Yet, the application of the Jacobi model and the insights that follow from it may be relevant in other cases, such as inline communication and even wireless communication. While a constant can be applied to account for the average power loss in the medium, the randomness structure of the loss can be modeled using the Jacobi model. As \( m \) increases with respect to \( m_t, m_r \), the randomness of the absolute received power increases. Evidently, in typical wireless communication, a large fraction of the energy is not captured, and so the channel can be modeled as a small submatrix of a large unitary matrix. Indeed, it will be shown that as \( m \) becomes larger in comparison to \( m_t, m_r \), the Jacobi model (up to a normalizing constant) approaches the Rayleigh model.

This paper is organized as follows. We start by defining the system model and presenting the channel statistics in Section II. An interesting transition threshold is revealed: when the number of addressed paths is large enough, so that \( K = m_t + m_r - m > 0 \), the statistics of the problem changes. Using this observation, we give analytic expressions for the ergodic capacity in Section III. In Section IV, we analyze the outage probabilities in the nonergodic channel and show that for \( k > 0 \), a strictly zero-outage probability is obtainable for \( k \) degrees of freedom. Following this finding, we present in Section V a new communication scheme which exploits a channel state feedback to achieve zero-outage probability. Section VI discusses the DMT of the channel where we show an absorbing difference in the maximum diversity gain between the Rayleigh fading and Jacobi channels. Section VIII discusses the results.

### II. SYSTEM MODEL AND CHANNEL STATISTICS

We consider an SDM system that supports \( m \) spatial propagation paths. In tribute to optical communication, in particular multimode optical fibers, the initial motivation for this work, we shall refer to these links as modes. Assuming a unitary coupling among all transmission modes, the overall transfer matrix \( \mathbf{H} \) can be described as an \( m \times m \) unitary matrix, where each entry \( \mathbf{H}_{ij} \) represents the complex path gain from transmitted mode \( i \) to received mode \( j \). We further assume a uniformly distributed unitary coupling, that is, \( \mathbf{H} \) is drawn uniformly from the ensemble of all \( m \times m \) unitary matrices (Haar distributed). Considering a communication system where \( m_t \leq m \) and \( m_r \leq m \) modes are being addressed by the transmitter and receiver, respectively, the effective transfer matrix is a truncated version of \( \mathbf{H} \).

Under these conditions, the channel can be described as

\[
\mathbf{y} = \sqrt{\rho} \mathbf{H}_{11} \mathbf{x} + \mathbf{z} \tag{1}
\]

where the vector \( \mathbf{x} \) containing \( m_t \) complex components represents the transmitted signal, the vector \( \mathbf{y} \) containing \( m_r \) complex components represents the received signal, and \( \mathbf{z} \) accounts for the presence of additive Gaussian noise. The \( m_r \) components of \( \mathbf{z} \) are statistically independent, circularly symmetric complex zero-mean Gaussian variables of unit variance \( \mathcal{N}(0,1) \). The components of \( \mathbf{x} \) are constrained such that the average energy of each component is equal to 1, i.e., \( \mathbb{E}(|x_j|^2) = 1 \) for all \( j \).

The term \( \rho \geq 0 \) is proportional to the power per excited mode so that it equals to the signal-to-noise ratio (SNR) in the single mode case \((m = 1)\). The matrix \( \mathbf{H}_{11} \) is a block of size \( m_r \times m_t \) within the \( m \times m \) random unitary matrix \( \mathbf{H} \).

\[
\mathbf{H} = \begin{bmatrix} \mathbf{H}_{11} & \mathbf{H}_{12} \\ \mathbf{H}_{21} & \mathbf{H}_{22} \end{bmatrix} \tag{2}
\]

As a first stage in our analysis, we establish the relation between the transfer matrix \( \mathbf{H}_{11} \) and the Jacobi ensemble of random matrices [1]–[3]. Limiting our discussion to complex matrices, we state the following definitions.

**Definition 1 (Gaussian Matrices):** \( \mathcal{G}(m, n) \) is an \( m \times n \) matrix of i.i.d complex entries distributed as \( \mathcal{CN}(0,1) \).

**Definition 2 (Wishart Ensemble):** \( \mathcal{W}(m, n) \), where \( m > n \), is an \( n \times n \) Hermitian matrix which can be constructed as \( A^\dagger A \), where \( A = \mathcal{G}(m, n) \).

**Definition 3 (Jacobi Ensemble):** \( \mathcal{J}(m_1, m_2, n) \), where \( m_1, m_2 \geq n \), is an \( n \times n \) Hermitian matrix which can be constructed as \( A(A + B)^{-1} \), where \( A \) and \( B \) are \( \mathcal{W}(m_1, n) \) and \( \mathcal{W}(m_2, n) \), respectively.

The first two definitions are related to wireless communication [7]. We claim here that the third classical ensemble, the Jacobi ensemble, is relevant to this channel model by relating its eigenvalues to the singular values of \( \mathbf{H}_{11} \). To that end, we quote the well-known [1], [4] joint probability density function (PDF) of the ordered eigenvalues \( 0 \leq \lambda_1 \leq \cdots \leq \lambda_n \leq 1 \) of the Jacobi ensemble \( \mathcal{J}(m_1, m_2, n) \)

\[
\mathcal{J}(\lambda_1, \ldots, \lambda_n) = K_{m_1, m_2, n}^{-1} \prod_{i=1}^{n} \lambda_i^m (1 - \lambda_i)^{m - n} \prod_{i < j} (\lambda_i - \lambda_j)^{2} \tag{3}
\]

where \( K_{m_1, m_2, n} \) is a normalizing constant. We say that \( n \) variables follow the law of the Jacobi ensemble \( \mathcal{J}(m_1, m_2, n) \) if their joint distribution follows (3).

We shall now present the explicit distribution of the channel’s singular values by distinguishing between the following two cases.

\(^1\)The constant per-mode power constraint, as opposed to the constant total power constraint often used in wireless communication, is motivated by the optical fiber nonlinearity limitation. Nevertheless, the total power constraint will be considered as well when needed.
A. Case I—$m_t + m_r \leq m$

In [25, Th. 1.5], it was shown that for $m_t, m_r$ satisfying the conditions $m_t < m_r$ and $m_t + m_r < m$, the eigenvalues of $\mathbf{H}_{11}^{\dagger} \mathbf{H}_{11}$ have the same distribution as the eigenvalues of the Jacobi ensemble $\mathcal{J}(m_r - m_t, m - m_t, m_t)$. For $m_t, m_r$ satisfying $m_t > m_r$ and $m_t + m_r \leq m$, since $\mathbf{H}_{11}^{\dagger}$ share the same distribution with $\mathbf{H}$, the eigenvalues of $\mathbf{H}_{11}^{\dagger} \mathbf{H}_{11}$ follow the law of the Jacobi ensemble $\mathcal{J}(m_t, m - m_t, m_r)$.

Combining these two results, we can say that the squared nonzero singular values of $\mathbf{H}_{11}$ have the same distribution as the eigenvalues of the Jacobi ensemble $\mathcal{J}(m_{\text{max}}, m - m_{\text{max}}, m_{\text{min}})$, where here and throughout this paper we denote $m_{\text{max}} = \max\{m_t, m_r\}$ and $m_{\text{min}} = \min\{m_t, m_r\}$.

B. Case II—$m_t + m_r > m$

When the sum of transmit and receive modes, $m_t + m_r$, is larger than the total available modes, $m$, the statistics of the singular values change. Clearly, when $m_{\text{max}} = m_{\text{min}} = m$, all singular values are 1. Thus, having in mind that the columns of $\mathbf{H}$ are orthonormal, one can think of $m_{\text{max}} + m_{\text{min}} > m$ as a transition threshold in which the size of $\mathbf{H}$ is large enough with respect to the size of the complete unitary matrix to change the singularity statistics. The following Lemma provides the joint distribution of the singular values of $\mathbf{H}_{11}$, showing that for any realization of $\mathbf{H}_{11}$, there are $m_t + m_r - m$ singular values which are 1. This lemma is a corollary of a result of Paige and Saunders [26]; however, its proof is given here for completeness.

**Lemma 1:** Let $\mathbf{H}$ be an $m \times m$ unitary matrix, divided into blocks as in (2), where $\mathbf{H}_{11}$ is an $m_r \times m_r$ block with $m_t + m_r > m$. Then, $m_t + m_r - m$ eigenvalues of $\mathbf{H}_{11}^{\dagger} \mathbf{H}_{11}$ are 1, $m_t - m_{\text{min}}$ are 0, and $m - m_{\text{max}}$ equal to the nonzero eigenvalues of $\mathbf{H}_{22}^{\dagger} \mathbf{H}_{22}$; if $\mathbf{H}$ is Haar distributed, these $m - m_{\text{max}}$ eigenvalues follow the law of the Jacobi ensemble $\mathcal{J}(m - m_{\text{min}}, m_{\text{min}}, m - m_{\text{max}})$.

**Proof:** Since $\mathbf{H}$ is unitary, we can write

$$\mathbf{H}_{11}^{\dagger} \mathbf{H}_{11} + \mathbf{H}_{22}^{\dagger} \mathbf{H}_{22} = \mathbf{I}_{m_t}$$

and

$$\mathbf{H}_{21}^{\dagger} \mathbf{H}_{21} + \mathbf{H}_{22}^{\dagger} \mathbf{H}_{22} = \mathbf{I}_{m_r}.$$  \hspace{1cm} (5)

Let $\{\lambda_{i}^{(1)}\}_{i=1}^{m_t}$ and $\{\lambda_{i}^{(2)}\}_{i=1}^{m_r}$ be the eigenvalues of $\mathbf{H}_{11}^{\dagger} \mathbf{H}_{11}$ and $\mathbf{H}_{22}^{\dagger} \mathbf{H}_{22}$, respectively. From (4), we can write

$$\lambda_{i}^{(1)} = 1 - \lambda_{i}^{(2)} \quad \forall i = 1, \ldots, m_t.$$  \hspace{1cm} (6)

Since $\mathbf{H}_{11}$ is a block of size $(m - m_r) \times m_t$ where $m - m_r < m$, $\mathbf{H}_{22}^{\dagger} \mathbf{H}_{22}$ has (at least) $m_t + m_r - m$ zero eigenvalues. Following (6), $\mathbf{H}_{11}^{\dagger} \mathbf{H}_{11}$ has $m_t + m_r - m$ eigenvalues which are 1. Now, let $\{\lambda_{i}^{(21)}\}_{i=1}^{m_t - m_r}$ and $\{\lambda_{i}^{(22)}\}_{i=1}^{m_r - m}$ be the eigenvalues of $\mathbf{H}_{21}^{\dagger} \mathbf{H}_{21}$ and $\mathbf{H}_{22}^{\dagger} \mathbf{H}_{22}$, respectively. From (5), we can write

$$\lambda_{i}^{(21)} = 1 - \lambda_{i}^{(22)} \quad \forall i = 1, \ldots, m - m_r.$$  \hspace{1cm} (7)

Since for any matrix $A$, $A^{\dagger} A$ and $A A^{\dagger}$ share the same nonzero eigenvalues, we can combine (6) and (7) to conclude that the additional $m - m_r$ eigenvalues of $\mathbf{H}_{11}^{\dagger} \mathbf{H}_{11}$ are equal to the $m - m_r$ eigenvalues of $\mathbf{H}_{22}^{\dagger} \mathbf{H}_{22}$. Note that $m - m_{\text{min}}$ of them are 0. Since the above arguments hold for any unitary matrix, and since $\mathbf{H}_{22}$ is a block of size $(m - m_r) \times (m - m_l)$, when $\mathbf{H}$ is Haar distributed, the results of Section II-A can be applied, which completes the proof.

**Lemma 1** reveals an interesting algebraic phenomenon: $k = \max\{m_t + m_r - m, 0\}$ singular values of $\mathbf{H}_{11}$ are 1 for any realization of $\mathbf{H}$. This provides some powerful results in the context of Jacobi fading channels. For example, the channel’s power $\|\mathbf{H}_{11}\|_F^2$, where $\|A\|_F$ denotes the Frobenius norm of $A$, is guaranteed to be at least $k$. Furthermore, $\mathbf{H}_{11}$ always comprises an unfaded $k$-dimensional subspace. In what follows, we show that this implies a lower bound on the ergodic capacity, an achievable zero-outage probability, and an “unbounded” diversity gain for certain rates.

III. ERGODIC CASE

In the ergodic scenario, the channel is assumed to be rapidly changing so that the transmitted signal samples the entire channel statistics. We further assume that the channel realization at each symbol time is known only at the receiver end. It is well known [6] that the channel capacity in that case is achieved by taking $\mathbf{x}$ to be a vector of circularly symmetric complex zero-mean Gaussian components, and is given by

$$C(m_t, m_r, m; \rho) = \max_{Q:Q \succeq 0} \mathbb{E}[\log \det(I_{m_r} + \rho \mathbf{H}_{11}^{\dagger} \mathbf{H}_{11})]$$  \hspace{1cm} (8)

where the maximization is over all covariance matrices of $\mathbf{x}$, $Q$, that satisfy the power constraints. Now, the capacity in (8) also satisfies

$$C(m_t, m_r, m; \rho) = \max_{Q:Q \succeq 0} \mathbb{E}[\log \det(I_{m_r} + \rho \mathbf{H}_{11}^{\dagger} \mathbf{H}_{11})]$$  \hspace{1cm} (9)

where it is well known [6, Th. 1] that if the distribution of $\mathbf{H}_{11}$ is invariant under unitary permutations, $Q = I_{m_r}$ is the optimal choice for (9). Since $\mathbf{H}$ is Haar distributed, that is invariant under unitary permutations, also $\mathbf{H}_{11}$ is invariant under unitary permutations. Thus, $Q = I_{m_r}$ is the optimal choice for (8) and by using the following equation:

$$\det(I_{m_r} + \rho \mathbf{H}_{11}^{\dagger} \mathbf{H}_{11}) - \det(I_{m_r} + \rho \mathbf{H}_{11}^{\dagger} \mathbf{H}_{11})$$

we can conclude that the ergodic capacity is given by

$$C(m_t, m_r, m; \rho) = \mathbb{E}[\log \det(I_{m_r} + \rho \mathbf{H}_{11}^{\dagger} \mathbf{H}_{11})].$$  \hspace{1cm} (10)

A. Case I—$m_t + m_r \leq m$

The following theorem gives an analytical expression to the ergodic capacity for cases where $m_t + m_r \leq m$. Using the joint distribution of the eigenvalues of the Jacobi ensemble, we
Fig. 1. Ergodic capacity, normalized by $C(1,1,1;\rho) = \log(1+\rho)$, as a function of $\rho$. In (a), the number of supported modes is fixed $m = 4$, various numbers of transmit $\times$ receive modes; in (b), the number of addressed modes is fixed $m_t = m_r = 2$, various values of supported modes $m$. 

associate the ergodic capacity with the Jacobi polynomials [27, 8.96].

**Theorem 1:** The ergodic capacity of the channel defined in (1) with $m_t, m_r$ satisfying $m_t + m_r \leq m$ reads

$$C(m_t, m_r, m; \rho) = \int_0^1 \lambda^\alpha (1-\lambda)^\beta \times \log(1 + \lambda \rho) \sum_{k=0}^{m/m_{\alpha,\beta} - 1} b_{k,\alpha,\beta}^k \left( P_k^{(\alpha,\beta)}(1 - 2\lambda) \right)^2 d\lambda$$

where $P_k^{(\alpha,\beta)}(x)$ are the Jacobi polynomials

$$P_k^{(\alpha,\beta)}(x) = \frac{(\frac{1}{2} + k)!}{k! (k + \alpha + \beta)!} (1 - x)^{-\alpha} (1 + x)^{-\beta} x^k$$

and $\alpha = m_r - m_t$, $\beta = m - m_t - m_r$.

**Proof:** See Appendix A, where the Gaudin–Mehta method [28] is applied to analyze the ergodic capacity.

**B. Case II—$m_t + m_r > m$**

Applying Lemma 1 to the channel capacity given in (10) readily results in the following theorem.

**Theorem 2:** The ergodic capacity of the channel defined in (1) with $m_t, m_r$ satisfying $m_t + m_r > m$ reads

$$C(m_t, m_r, m; \rho) = \{ m_t + m_r - m \} \log(1 + \rho) + \sum_{i=1}^{m} \log(1 + \rho \lambda_i)$$

where $\{\lambda_i\}_{i=1}^{m}$ are the eigenvalues of $H_{11}^\dagger H_{11}$. According to Lemma 1, $m_t + m_r - m$ eigenvalues are 1 and the rest are equal to the $m - m_r$ eigenvalues of $H_{22}^\dagger H_{22}$. Applying that into (15) results

$$C(m_t, m_r, m; \rho) = \{ m_t + m_r - m \} \log(1 + \rho) + E[\log \det(1 - m_r - \rho H_{22}^\dagger H_{22})].$$

Note that the second term on the right-hand side of (13), $C(m_t, m_r, m - m_t, m; \rho)$, is given by Theorem 1 and reduces to 0 when $m_t$, or $m_r$ is equal to $m$. Thus, (13) suggests that for systems with $k = m_t + m_r - m > 0$, the ergodic capacity is the sum capacities of $k$ unfaded SISO capacities and a Jacobi MIMO channel with $m - m_r$ transmit modes and $m - m_t$ receive modes. Fig. 1(a) depicts the ergodic capacity as a function of $\rho$ for $m = 4$ and various combinations of $m_t, m_r$ (note that the ergodic capacity, in our case, is symmetric in $m_t, m_r$; thus, all combinations are plotted). As is evident from the figure, a capacity equivalent to $k$ SISO channels is guaranteed in all cases. In Fig. 1(b), the ergodic capacities for $m_t = m_r = 2$ and various values of supported modes are plotted. Note that as $m$ increases, the power loss increases and the ergodic capacity becomes smaller. Unlike the common practice of expressing the capacity in terms of the received SNR, here the capacities are presented as a function of $\rho$. This normalizes the capacity expression to reflect the capacity loss due to power loss including power leaked into the unobserved modes. In particular, this presentation enables to examine the total effect (capacity loss) of increasing $m$. See further discussion in Section VII.

**IV. NONERGODIC CASE**

In the nonergodic scenario, the channel matrix is drawn randomly but rather assumed to be constant within the entire transmission period of each code frame. The figure of merit in the nonergodic case is the outage probability defined as the probability that the mutual information induced by the channel realization is lower than the rate $R$ at which the link is chosen to
operate. Note that we assume that the channel instantiation is unknown at the transmitter; thus, it cannot adapt the transmission rate. However, the channel is assumed to be known at the receiver end. By taking an input vector of circularly symmetric complex zero-mean Gaussian variables with covariance matrix $Q$, the mutual information is maximized and the outage probability can be expressed as

$$P_{\text{out}}(m_t, m_r; m; R) = \inf_{Q \geq 0} \Pr \left[ \log \det \left( I_{m_r} + \rho \mathbf{H}_{11} \mathbf{H}_{11}^\dagger \right) < R \right]$$  \hspace{1cm} (17)$$

where the minimization is over all covariance matrices $Q$ satisfying the power constraints. Since the statistics of $\mathbf{H}_{11}$ are invariant under unitary permutations, the optimal choice of $Q$, when applying constant per-mode power constraint, is simply the identity matrix. We note that when imposing total power constraint, the optimal choice of $Q$ may depend on $R$ and $\rho$ and in general is unknown, even for the Rayleigh channel. Nevertheless, when $\rho \gg 1$, the identity matrix is approximately the optimal $Q$ (see Section VI). Thus, in the following, we make the simplified assumption that the transmitted covariance matrix is the commonly used choice $Q = I_{m_r}$.

Now, let the transmission rate be $R = r \log(1 + \rho)\text{ bps/Hz}$ and let $\lambda = \{\lambda_i\}_{i=1}^{m_{\min}}$ be the ordered nonzero eigenvalues of $\mathbf{H}_{11}^\dagger \mathbf{H}_{11}$; we can write

$$P_{\text{out}}(m_t, m_r; m; r \log(1 + \rho)) = \Pr \left[ \log \det \left( I_{m_r} + \rho \mathbf{H}_{11}^\dagger \mathbf{H}_{11} \right) < R \right] = \Pr \left[ \prod_{i=1}^{m_{\max}} (1 + \rho \lambda_i) < (1 + \rho)^r \right]$$  \hspace{1cm} (18)$$

and evaluate this expression by applying the statistics of $\lambda$.

A. Case $1 - m_t + m_r \leq m$

Using (3), we can apply the joint distribution of $\lambda$ into (19) to get

$$P_{\text{out}}(m_t, m_r, m; r \log(1 + \rho)) = K^{-1}_{m_r, m, m} \times$$

$$\int_{B} \prod_{i=1}^{m_{\min}} \lambda_i^{m_i - m_i} (1 - \lambda_i)^{m_r - m_i} \prod_{i<j} (\lambda_i - \lambda_j)^2 d\lambda$$  \hspace{1cm} (20)$$

where $K_{m_r, m, m}$ is a normalizing factor and $B$ describes the outage event

$$B = \left\{ \lambda : \prod_{i=1}^{m_{\min}} (1 + \rho \lambda_i) < (1 + \rho)^r \right\}.$$  

This gives an analytical expression to the outage probability. See Fig. 3 and the example below.

Example 1: Suppose $m_t = 1$ and $m_r, m$ satisfy $m \geq 1 + m_r$. In that case, the outage probability is given by

$$P_{\text{out}}(1, m_r, m; R) =$$

$$K_{1, m_r, m} \int_{0}^{(2^R - 1)/\rho} \lambda^{m_r - 1}(1 - \lambda)^{m - m_r - 1} d\lambda.$$  \hspace{1cm} (21)$$

Thus, we can write

$$P_{\text{out}}(1, m_r, m; R) = B((2^R - 1)/\rho; m_r, m - m_r)$$

$$B(1; m_r, m - m_r)$$  \hspace{1cm} (22)$$

where $B(x; a, b)$ is the incomplete beta function. Hence, to support an outage probability smaller than $\epsilon$, $R$ and $\rho$ have to satisfy

$$\rho \frac{1}{2^R - 1} \geq B^{-1}(\epsilon B(1; m_r, m - m_r); m_r, m - m_r)$$  \hspace{1cm} (23)$$

where $B^{-1}(x; a, b)$ is the inverse function of $B(x; a, b)$. We denote the right-hand side of (23) by $\rho_{\text{norm}}$. Therefore, $\rho_{\text{norm}}$ is the normalized SNR at the transmitter, is proportional to the received normalized SNR, and essentially measures the minimal additional power required to support a target rate $R$ with outage probability smaller than $\epsilon$ (additional power over the minimal required in SISO unfading channel $(m = m_r)$). As $\rho_{\text{norm}}$ is smaller, one can afford higher data rate or smaller $\rho$ (smaller transmission power).

In Fig. 2, we plot $\rho_{\text{norm}}$ as a function of $m_r/m$ for various numbers of available modes $m$ and desired outage probabilities $\epsilon$. For fixed $m$ and $m_r/m$, $\rho_{\text{norm}}$ increases as $\epsilon$ decreases (since more power or lower data rate are needed to achieve smaller outage probability). For fixed $\epsilon$ and $m$, $\rho_{\text{norm}}$ decreases as $m_r/m$ increases (since more modes are addressed by the receiver; therefore, the power loss decreases). This is also true as $m$ increases, while $\epsilon$ and $m_r/m$ are fixed (since the diversity at the receiver increases, see Section VI). Note that for $m_r/m = 1$, there is no power loss and we get $\rho_{\text{norm}} = 1$, that is, the minimal transmission power required to support the rate $R$, for any $\epsilon$, is $\rho = 2^R - 1$.

B. Case II—$m_t + m_r > m$

Applying Lemma 1 to (19) gives the following.

Theorem 3: The outage probability of the channel defined in (1), with $m_t, m_r$ satisfying $m_t + m_r > m$, satisfies

$$P_{\text{out}}(m_t, m_r, m; r \log(1 + \rho)) =$$

$$P_{\text{out}}(m - m_r, m - m_t, m; r \log(1 + \rho)).$$  \hspace{1cm} (24)$$
where $\hat{r}$ is the larger between $r - (m_t + m_r - m)$ and 0.

Proof: According to (19), the outage probability is given by

$$P_{\text{out}}(m_t, m_r, m; r \log(1 + \rho)) = \Pr\left[\prod_{i=1}^{m} (1 + \rho \lambda_i) < (1 + \rho)^{r}\right]$$  \hspace{1cm} (25)

where $\{\lambda_i\}_{i=1}^{m}$ are the eigenvalues of $H_{ij}^{\dagger} H_{ij}$. Applying Lemma 1, we get

$$P_{\text{out}}(m_t, m_r, m; r \log(1 + \rho)) = \Pr\left[\prod_{i=1}^{m-m_r} (1 + \rho \hat{\lambda}_i) < (1 + \rho)^{r-(m_t+m_r)-m}\right]$$  \hspace{1cm} (26)

where $\{\hat{\lambda}_i\}_{i=1}^{m-m_r}$ are the eigenvalues of $H_{ij}^{\dagger} H_{22}$. When $\hat{r} = r - (m_t + m_r - m) < 0$, we get $P_{\text{out}}(m_t, m_r, m; r \log(1 + \rho)) = 0$.

Note that the right-hand side drops to 0, when $m_r$, or $m_t$, equals $m$. Most importantly, when $r < m_t + m_r - m$, $\hat{r} = 0$, implying that for such rates zero-outage probability is achievable. In addition, when $r \geq m_t + m_r - m > 0$, (24) implies that the outage probability is identical to that of a channel with $m_t$ modes addressed by the transmitter and $m_r$ modes addressed by the receiver, which is designed to support a transmission rate equivalent to $\hat{r}$ single-mode channels. Thus, the right-hand side of (24) applies to (20). In Fig. 3(a), we show an exemplary calculation of the outage probability. These curves, obtained from our analysis, were plotted in the same form as the numerical results reported in [23]. Note how the outage probability abruptly drops to 0 whenever $r$ becomes smaller than $m_t + m_r - m$. Also note that the outage probability is symmetric in $m_t, m_r$ since we applied a constant per-mode power constraint; thus, all combinations of $m_t, m_r$ are plotted in Fig. 3(a). In Fig. 3(b), outage probability curves are plotted for $m_t = m_r = 2$ and various values of supported modes, $m$.

Note that as $m$ is larger, more power is lost in the unaddressed modes; therefore, as evident from the figure, the outage probability increases.

V. ACHIEVING THE NO-OUTAGE PROMISE

In the previous section, we saw that for systems satisfying $k = m_t + m_r - m > 0$, a zero-outage probability is achievable for any transmission rate below $R = k \log(1 + \rho)$. In this section, we present a new communication scheme that achieves this promise with a transmission rate arbitrarily close to $R = k \log(1 + \rho)$. Using simple manipulations, the scheme exploits a (delayed) channel state information (CSI) feedback to transform the channel into $k$ independent SISO channels, supporting $k$ streams (degrees of freedom) with zero-outage probability.

Let

$$H^{(i)} = \begin{bmatrix} H_{11}^{(i)} & H_{12}^{(i)} \\ H_{21}^{(i)} & H_{22}^{(i)} \end{bmatrix}$$

be the unitary matrix realization at channel use $i$, and let

$$\mathbf{x}^{(i)} = \sqrt{\rho} H_{11}^{(i)} \mathbf{z}^{(i)} + \mathbf{x}^{(i)}$$

be the received signal. We assume a perfect knowledge of $H_{11}^{(i)}$ at the receiver and a noiseless CSI feedback with a delay of a single channel use. Since $H^{(i)}$ is unitary, a matrix $H_{21}^{(i)}$ can be computed to complete $H_{21}^{(i)}$ into orthonormal columns. Therefore, we shall assume that the receiver noiselessly communicates this computed $H_{21}^{(i)}$ to the transmitter. Nevertheless, note that for $m_t + m_r - m > 1$ and certain matrix instantiations, the computed $H_{21}^{(i)}$ is not unique and can be chosen wisely (see Remark 4).

Now, let the transmitter excites the following signal from the addressed modes at each channel use $i = 1, \ldots, n$:

$$\mathbf{x}^{(i)} = \begin{bmatrix} x^{(i)}_1 \\ \vdots \\ x^{(i)}_{m_t+m_r-m} \\ H_{21}^{(i)} \mathbf{x}^{(i)}_{(i-1)} \end{bmatrix}$$
That is, the transmitter conveys \(m_t + m_r - m\) new information bearing symbols and \(\mathbf{H}_{21}^{(i-1)} \mathbf{x}^{(i-1)}\), a linear combination of the signal that was transmitted in the previous channel use (\(\mathbf{x}^{(0)}\) is a vector of zeros). Note that \(\mathbf{H}\) is unitary; thus, the power constraint is left satisfied.

We shall now assume that after the last signal \(\mathbf{y}^{(n)}\) is received, the receiver gets as a side information the following noisy measures:

\[
\mathbf{y}_{si} = \sqrt{\rho} \mathbf{H}_{21}^{(n)} \mathbf{x}^{(n)} + \mathbf{z}_{si},
\]

where the components of \(\mathbf{z}_{si}\) are i.i.d. \(\mathcal{CN}(0, 1)\). Thus, the receiver can linearly combine \(\mathbf{y}^{(n)}\) and \(\mathbf{y}_{si}\) in the following manner:

\[
\hat{\mathbf{y}}^{(n)} = \begin{bmatrix} \mathbf{H}_{11}^{(n)} \dagger \mathbf{H}_{21}^{(n)} \dagger \end{bmatrix} \begin{bmatrix} \mathbf{y}^{(n)} \\ \mathbf{y}_{si} \end{bmatrix}
\]

(28)

to yield

\[
\hat{\mathbf{y}}^{(n)} = \sqrt{\rho} \mathbf{y}^{(n)} + \tilde{\mathbf{z}}
\]

(29)

where the entries of \(\tilde{\mathbf{z}}\) are i.i.d. \(\mathcal{CN}(0, 1)\). We remind that the first \(m_t + m_r - m\) entries of \(\mathbf{y}^{(n)}\) are new information bearing symbols and the last entries are equal to \(\mathbf{H}_{21}^{(n-1)} \mathbf{x}^{(n-1)}\). Thus, the last \(m - m_r\) entries of \(\mathbf{y}^{(n)}\), denoted \(\hat{\mathbf{y}}\), satisfy

\[
\hat{\mathbf{y}} = \sqrt{\rho} \mathbf{H}_{21}^{(n-1)} \mathbf{x}^{(n-1)} + \tilde{\mathbf{z}}
\]

where \(\tilde{\mathbf{z}}\) are the last \(m - m_r\) entries of \(\tilde{\mathbf{z}}\). Again, the receiver can linearly combine \(\mathbf{y}^{(n-1)}\) and \(\hat{\mathbf{y}}\) as

\[
\hat{\mathbf{y}}^{(n-1)} = \begin{bmatrix} \mathbf{H}_{11}^{(n-1)} \dagger \mathbf{H}_{21}^{(n-1)} \dagger \end{bmatrix} \begin{bmatrix} \mathbf{y}^{(n-1)} \\ \hat{\mathbf{y}} \end{bmatrix}
\]

(30)

to yield measures of \(\mathbf{x}^{(n-1)}\) as in (29). Repeating this procedure for \(i = n - 1 \rightarrow 1\) results in \(m_t + m_r - m\) independent streams of measures

\[
\begin{bmatrix}
\mathbf{y}^{(1)} \\
\vdots \\
\mathbf{y}^{(n)}
\end{bmatrix}
= \begin{bmatrix}
\mathbf{H}_{21}^{(i-1)} \mathbf{x}^{(i-1)} & \cdots & \mathbf{H}_{21}^{(n)} \mathbf{x}^{(n)}
\end{bmatrix}
\]

The scheme above is feasible if the side information after channel use \(n\) is being conveyed by the transmitter through a neglectable number of channel uses (with respect to \(n\), see Remark 3). In that case, the receiver can construct \(m_t + m_r - m\) independent SISO channels, each with SNR \(\rho\). Thus, the scheme supports a rate arbitrarily close (as \(n\) is larger) to \((m_t + m_r - m) \log(1 + \rho)\) with zero-outage probability. Note that the scheme essentially completes the singular values of the channel to \(1\). This is feasible since \(m_t - m_r < m_t\); thus, at each channel use, the transmitter can transmit \(\mathbf{H}_{21}^{(i-1)} \mathbf{x}^{(i-1)}\), a signal of \(m - m_r\) entries, and new symbols.

The scheme presented above can be easily expanded to the case where the feedback delay is \(l\) channel uses. In that case, the transmitter conveys at each channel use \(m_t + m_r - m\) new information bearing symbols and \(\mathbf{H}_{21}^{(i-l)} \mathbf{x}^{(i-l)}\), a linear combination of the signal that was transmitted in \(l\) channel uses before. After channel use \(n\), the transmitter would have to convey \(l\) noisy measures of the last \(i\) signals, so that the receiver could construct \(m_t + m_r - m\) independent SISO channels. This can be done in a fixed number of channel uses (see Remark 3); thus, as \(n\) is larger, the transmission rate of the scheme approaches \((m_t + m_r - m) \log(1 + \rho)\).

### Remark 1 (Outdated Feedback):
Our scheme exploits a noiseless CSI feedback system to communicate a (possibly) outdated information—the channel realization in previous channel uses. Thus, the feedback is not required to be fast, that is, no limitations on the delay time \(l\). However, if \(l\) is smaller than the coherence time of the channel, the feedback may carry information about the current channel realization. Thus, the transmitter can exploit the up-to-date feedback to use more efficient schemes. Nevertheless, for systems with a long delay time (e.g., relatively long distance optical fibers), the channel can be regarded as nonergodic with an outdated feedback. In these cases, our scheme efficiently achieves zero-outage probability.

### Remark 2 (Simple Decoding):
The scheme linearly process the received signals to construct \(m_t + m_r - m\) independent streams of measures, each with SNR \(\rho\). This allows the decoding stage to be simple, where a SISO channel decoder can be used, removing the need for further MIMO signal processing.

### Remark 3 (Side Information Measures):
For a feedback with a delay of \(l\) channel uses, the transmitter has to convey \(\mathbf{H}_{21}^{(i)} \mathbf{x}^{(i)}\), for each \(i = n - (l - 1), \ldots, n\), such that the receiver can extract a vector of noisy measures with SNR that is not smaller than \(\rho\). This is feasible with a finite number of channel uses. For example, the repetition scheme can be used to convey these measures (see Section VI Example 2). Suppose each \(\mathbf{H}_{21}^{(i)} \mathbf{x}^{(i)}\) is conveyed to the receiver within \(N_{si}\) channel uses (e.g., for the repetition scheme \(N_{si} = m_t (m_r - m_r)\)). By taking large enough \(n\) (with respect to \(l \cdot N_{si}\)), one can approach the rate \((m_t + m_r - m) \log(1 + \rho)\).

### Remark 4 (Uniqueness of \(\mathbf{H}_{21}\)):
The scheme can be further improved to support even an higher data rate with zero-outage probability. For example, the last \(m_t - m_r\) entries of the transmitted signal at the first channel use can be used to excite information bearing symbols instead of the zeros symbols. Furthermore, as was mentioned above, when \(m_t + m_r - m > 1\), \(\mathbf{H}_{21}^{(i)}\) is not unique; there are many \((m - m_r) \times m_t\) matrices that complete the columns of \(\mathbf{H}_{21}^{(i)}\) to orthonormal vectors. Thus, the receiver can choose \(\mathbf{H}_{21}^{(i)}\) to be the one with the largest number of zeros rows. Now, at time \(i + 1\), the transmitter excites \(m_t + m_r - m\) new symbols and \(\mathbf{H}_{21}^{(i+1)} \mathbf{x}^{(i)}\), a retransmission of \(\mathbf{z}(i)\), the transmitted signal at time \(i\). With an appropriate choice of \(\mathbf{H}_{21}^{(i)}\), \(\mathbf{H}_{21}^{(i)} \mathbf{x}^{(i)}\) contains entries that are zero. Instead, these entries can contain additional new information bearing symbols. An open question is how to further enhance the data rate. One would like to exploit the feedback to approach the empirical capacity for any realization of \(\mathbf{H}_{11}\). Note that this rate is achievable with an up-to-date feedback. Further approaching this rate with an outdated feedback system (and with zero-outage probability) is left for future research.
VI. DIVERSITY MULTIPLEXING TRADEOFF

Using multiple modes/antennas is an important means to improve performance in optical/wireless systems. The performance can be improved by increasing the transmission rate or by reducing the error probability. A coding scheme can achieve both performance gains; however, there is a fundamental tradeoff between how much each can get. This tradeoff is known as the DMT. The optimal tradeoff for the Rayleigh fading channel was found in [29]. In this section, we seek to find the optimal tradeoff for the Jacobi channel.

To better understand the concepts of diversity and multiplexing gains in the Jacobi channel, we start with the following example.

Example 2 (Repetition Scheme): Suppose the transmitter excites the following \((m_t)\) entries signals in each \(m_t\) consecutive channel uses:

\[
\begin{bmatrix}
\mathbf{x}
\end{bmatrix}
\begin{bmatrix}
0 \\
0
\end{bmatrix}
\begin{bmatrix}
0 \\
0
\end{bmatrix}
\begin{bmatrix}
0 \\
0
\end{bmatrix}
\ldots
\begin{bmatrix}
0 \\
0
\end{bmatrix}
\begin{bmatrix}
\mathbf{x}
\end{bmatrix}
\begin{bmatrix}
\mathbf{0}
\end{bmatrix}
\begin{bmatrix}
\mathbf{0}
\end{bmatrix}
\ldots
\begin{bmatrix}
\mathbf{0}
\end{bmatrix}
\begin{bmatrix}
\mathbf{0}
\end{bmatrix}.
\]

Let us make the simplifying assumptions that \(\mathbf{x}\) is an uncoded QPSK symbol and that \(m_t \leq m_r\). (Similar results can be obtained also for \(m_t > m_r\) and for higher constellation sizes.)

We further assume that the channel realization is known at the receiver and is constant within the \(m_r\) channel uses. It can be shown that in that case, the average error probability satisfies

\[
P_e(\rho) = \mathbb{E}[\exp \left( -\frac{\rho}{2} \sum_{i=1}^{m_r} \lambda_i \right)]
\]

where the expectation is over \(\{\lambda_i\}_{i=1}^{m_r}\), the eigenvalues of \(\mathbf{H}_1^H \mathbf{H}_1\). Here and throughout the rest of the paper, we use \(\approx\) to denote exponential equality, i.e., \(f(\rho) \approx \rho^d\) denotes

\[
\lim_{\rho \to \infty} \frac{\log f(\rho)}{\log \rho} = d.
\]

Now, for \(m_t + m_r \leq m\), we can apply the joint distribution of the unordered eigenvalues of a Jacobi matrix \(J_{m_t \times m_r, m_r \times m_r}\) to write

\[
P_e(\rho) \approx \frac{K_{m_t,m_r,m_r}}{m_t!} \int_0^1 \ldots \int_0^1 \prod_{i=1}^{m_r} \lambda_i^{m_r} \times
\begin{bmatrix}
1 - \lambda_i
\end{bmatrix}^{m_r - m_r - m_r} e^{-\frac{\rho}{2} \sum_{i=1}^{m_r} \lambda_i^{m_r}}
\]

\[
(1 - \lambda_i)^{m_r - m_r - m_r} e^{-\frac{\rho}{2} \sum_{i=1}^{m_r} \lambda_i^{m_r}}
\]

\[
(1 - \lambda_i)^{m_r - m_r - m_r} e^{-\frac{\rho}{2} \sum_{i=1}^{m_r} \lambda_i^{m_r}}
\]

where \(\mathbf{H}_2^H \mathbf{H}_2\) denotes the signature of the permutation \(\sigma\). Applying (34) into (33) results (35), shown at the bottom of the page. It can be further shown that the right-hand side of (35) is dominated (for large \(\rho\)) by the term

\[
\sum_{A_1 \in \mathbb{S}_{m_t}} (-1)^{\text{sgn}(\sigma_1) + \text{sgn}(\sigma_2)} \prod_{i=1}^{m_r} \lambda_i^{\sigma_1(i) + \sigma_2(i) - 2} \prod_{i=1}^{m_r} \lambda_i^{m_r - (m_r + m_r)}
\]

where \(A_1 = m_r - m_t + \sigma_1(i) + \sigma_2(i) - 2\). Thus, for \(m_t + m_r \leq m\), the average error probability satisfies

\[
P_e(\rho) \approx \rho^{-\sum_{i=1}^{m_r} (m_r - m_t + 2i - 1)}
\]

\[
= \rho^{-m_r m_r}
\]

For \(m_t + m_r > m\), by applying Lemma 1 into (31), we get

\[
P_e(\rho) = e^\left( \frac{\rho (m_t + m_r - m)}{2} \right) \mathbb{E}[\exp \left( -\frac{\rho}{2} \sum_{i=1}^{m_r} \lambda_i \right)]
\]

\[
(35)
\]

Note that the term

\[
\prod_{1 \leq i < j \leq m_r} (\lambda_j - \lambda_i)
\]

is the determinant of the Vandermonde matrix

\[
\begin{bmatrix}
1 & \cdots & 1 \\
\lambda_1 & \cdots & \lambda_m \\
\vdots & \cdots & \vdots \\
\lambda_1^{m_r - 1} & \cdots & \lambda_m^{m_r - 1}
\end{bmatrix}
\]

Thus, we can write

\[
\prod_{1 \leq i < j \leq m_r} (\lambda_j - \lambda_i)^2
\]

\[
= \sum_{\sigma_1, \sigma_2 \in \mathbb{S}_{m_t}} (-1)^{\text{sgn}(\sigma_1) + \text{sgn}(\sigma_2)} \prod_{i=1}^{m_r} \lambda_i^{\sigma_1(i) + \sigma_2(i) - 2} \prod_{i=1}^{m_r} \lambda_i^{m_r - (m_r + m_r)}
\]

(34)

In Fig. 4, we present the average error probability versus \(\rho\) for \(m = 4\) and various combinations of \(m_t, m_r\) (the error probability is symmetric in \(m_t, m_r\); thus, all combinations of \(m_t, m_r\),
error probability with a smaller decaying order, that is, a smaller diversity gain. Thus, there is a tradeoff between diversity and multiplexing gains.

We now turn to analyze the DMT in the Jacobi model. To that end, we formalize the concepts of diversity gain and multiplexing gain by quoting some definitions from [29].4

**Definition 4:** Let a scheme be a family of codes \( \{ \mathcal{C}(\rho) \} \) of block length \( l \), one at each \( \rho \) level. Let \( R(\rho) \) (bps/Hz) be the rate of the code \( \mathcal{C}(\rho) \). A scheme \( \{ \mathcal{C}(\rho) \} \) is said to achieve spatial multiplexing gain \( r \) and diversity gain \( d \) if the data rate satisfies

\[
\lim_{\rho \to \infty} \frac{R(\rho)}{\log \rho} = r
\]

and the average error probability satisfies

\[
\lim_{\rho \to \infty} \frac{P_e(\rho)}{\log \rho} = -d.
\]

For each \( r \), define \( d^*(r) \) to be the supremum of the diversity advantage achieved over all schemes.

A. Case \( l - m_t + m_r \leq m \)

The following theorem provides the optimal DMT of a Jacobi channel with \( m_t \), \( m_r \), and \( m \) satisfying \( m_t + m_r \leq m \).

**Theorem 4:** Suppose \( l \geq m_t + m_r - 1 \). The optimal DMT curve \( d^*(r) \) for the channel defined in (1), with \( m_t, m_r \) satisfying \( m_t + m_r \leq m \), is given by the piecewise linear function that connects the points \( (k, d^*(k)) \) for \( k = 0, 1, \ldots, m_{\text{min}} \), where

\[
d^*(k) = (m_t - k)(m_r - k).
\]

**Proof:** See Appendix B.

Theorem 4 suggests that for \( m_t + m_r \leq m \), the optimal DMT curve does not depend on \( m \). Note that \( m \) relates to the extent in which the elements of \( \mathbf{H}_{11} \) are mutually independent—the dependence is smaller as \( m \) is larger. Hence, at high SNR (large \( \rho \)), the dependence between the path gains has no effect on the decaying order of the average error probability.

Furthermore, the optimal DMT is identical to the optimal tradeoff in the analogous Rayleigh channel (where the path gains are independent).

\[\text{Note that in [29], the definitions in 4 were made with respect to the average SNR at each receive mode, denoted } \bar{\rho}. \text{ However, since } \bar{\rho} = \rho E[\|\mathbf{r}[\mathbf{H}_{11}]\|/m_r], \text{ where } Q \text{ is the transmitted covariance matrix, we can write } \lim_{\rho \to \infty} \log \bar{\rho} = \lim_{m \to \infty} \log \rho. \text{ Hence, the definitions in 4 coincide with those in [29].}\]
B. Case II—$m_t + m_r > m$

According to Theorem 3, a zero-outage probability is achievable for rates below $(m_t + m_r - m) \log(1 + \rho)$. Hence, for any $(m_t + m_r - m) > \delta > 0$, there is a scheme $\{\mathcal{C}(\rho)\}$ with code rates $[m_t + m_r - m - \delta] \log(1 + \rho)$ that achieves a zero-outage probability; therefore, assuming $l$ be very large achieves an exponentially decaying error probability. In that case, the discussion about diversity is no longer of relevance. Nonetheless, one can think of the gain as infinite. This reveals an interesting difference between the Jacobi and Rayleigh channels—the maximum diversity gain is “unbounded” as opposed to $m_t m_r$ in the later case.

**Theorem 5:** The optimal DMT curve $d^*(r)$ for the channel defined in (1), with $m_t, m_r$ satisfying $m_t + m_r > m$, is given by

$$d^*(r) =
\begin{cases}
    d^*_{\text{risual}}(r - (m_t + m_r - m)) & , r \geq m_t + m_r - m \\
    \infty & , r < m_t + m_r - m
\end{cases}$$

(40)

$d^*_{\text{risual}}(r)$ is the optimal curve for a Jacobi channel with $m - m_r$ transmit and $m - m_t$ receive modes.

**Proof:** At high SNR, in terms of minimal outage probability, we can take the covariance matrix of the transmitted signal to be $Q = \mathbf{1}_m$; see Appendix B. Thus, Theorem 3 can be applied: for $r < m_t + m_r - m$, the minimal outage probability is zero; hence, the error probability turns exponentially decaying with $\rho$ (assuming $l$ is very large); for $r \geq m_t + m_r - m$, the outage probability equals the outage probability for $r = \hat{r} = r - (m_t + m_r - m)$ in a system with $m - m_r$ transmit and $m - m_t$ receive modes. Noting that at high SNR the error probability is dominated by the outage probability (see Appendix B) completes the proof.

Note that $d^*_{\text{risual}}(r)$ in (40) is given by Theorem 4 for any block length $l$ satisfying $l \geq m_t + m_r - 1$. Fig. 5 depicts the optimal DMT curve for $m_t = m_r = 4$ and various numbers of supported modes $m$.

In the following example, we try to illuminate the concept of infinite diversity gain.

**Example 3 ($m_t = m_r = 2$):** We consider the $2 \times 2$ Alamouti scheme [34]. Assuming a code block of length $l \geq 3$ and rate $R = r \log \rho$ (bps/Hz), the transmitter excites in each two consecutive channel uses two information bearing symbols in the following manner:

$$\begin{bmatrix}
x_1 \\
x_2
\end{bmatrix}; \begin{bmatrix}
-x_2^* \\
x_1^*
\end{bmatrix}.$$
Maximum likelihood decoding linearly combines the received measures and yields the following equivalent scalar channels:

\[ y_i = \sqrt{|H_{11}|^2 \rho} z_i + z_i, \quad \forall i = 1, 2 \]  

(41)

where each \( z_i \) is i.i.d. \( \mathcal{CN}(0, 1) \) independent of \( x_i \) and \( H_{11} \). The probability for an outage event is given by

\[ P_{\text{out}}(2, 2, m; R) = \Pr \left[ \log(1 + \|H_{11}\|^2 \rho) < r \log \rho \right] \]

(42)

\[ = \Pr \left[ \|H_{11}\|^2 F < \rho^{-(1-r)^+} \right]. \]

(43)

Now, in the Rayleigh channel, \( |H_{11}|^2 F \) is chi-square distributed with \( 2m_1 m_r \) degrees of freedom. In that case, as was shown in [29], the 2 x 2 Alamouti scheme can achieve maximum diversity gain of 4. However, in the Jacobi channel:

1) for \( m = 2 \), we have \( |H_{11}|^2 F = 2 \) (\( H_{11} \) is unitary).
2) for \( m = 3 \), we have \( |H_{11}|^2 F \geq 1 \) (by Lemma 1).
3) for \( m \geq 4 \), there is always a nonzero probability for an outage event.

Therefore, for \( m = 2 \) and \( m = 3 \), for any \( r \leq 1 \), we get equivalent unfading scalar channels with strictly zero-outage probability and one can think of the maximum diversity gain as infinite. For \( m \geq 4 \), it can be shown that the maximum diversity gain is 4 and the DMT curve linearly connects the points \( (1/2, 0) \) and \( (0, 4) \).

In Example 2, we saw that for multiplexing gain \( r = 0 \), the repetition scheme achieves a diversity gain of \( m_1 m_r \) for systems satisfying \( m_1 + m_r \leq m \) and an unbounded gain for systems satisfying \( m_1 + m_r > m \). Thus, for \( m \geq 4 \), the maximum diversity gain of this scheme is 4 and it can be shown that the DMT curve linearly connects the points \((1/2, 0)\) and \((0, 4)\). For \( m = 2 \) and \( m = 3 \), we get an unbounded diversity gain for any multiplexing gain below \( r = 1/2 \).

In Fig. 6, we compare these DMT curves to the optimal curves. Note that for \( m = 3 \), the Alamouti scheme achieves the optimal DMT for \( r = 1 \).

VII. Relation to the Rayleigh Model

The Jacobi fading model is defined by the transfer matrix \( H_{11} \), a truncated \( m_r \times m_r \) version of a Haar-distributed \( m \times m \) unitary matrix. We shall now examine the case, where \( m \) is very large with respect to \( m_1 \) and \( m_r \).

Assuming \( m_r \leq m_r \) and \( m_t + m_r \leq m \), the statistics of the squared singular values of the Jacobi channel model follow the law of the Jacobi ensemble \( J(m_r, m - m_r, m) \). This ensemble can be constructed as

\[ G_1^\dagger G_1 (G_1^\dagger G_1 + G_2^\dagger G_2)^{-1} \]

(44)
where $G_1$ and $G_2$ are $m_r \times m_t$ and $(m - m_r) \times m_t$ independent Gaussian matrices. Thus, the squared singular values of $H_{11}$ share the same distribution with the eigenvalues of (44). Intuitively, in terms of the singularity statistics, the Jacobi channel can be viewed as an $m_r \times m_t$ subchannel of an $m \times m_t$ normalized Gaussian channel. Furthermore, for $m \gg m_t$, we have

$$G_1^\dagger (G_1^\dagger G_1 + G_2^\dagger G_2)^{-1} G_1^\dagger G_1 \approx G_1^\dagger G_1 (mE[G_2^\dagger G_2])^{-1}$$

(45)

$$= \frac{1}{m} G_1^\dagger G_1$$

(46)

where in (45) we applied the law of large numbers ($g$ is a vector of $m_t$ independent components, each distributed $CN(0, 1)$). In the same manner, for $m_r > m_r, m_t + m_r < m$ and $m \gg m_t$, the squared singular values of the Jacobi channel share the same distribution with the following ensemble of random matrices:

$$G_1^\dagger (G_1^\dagger G_1 + G_2^\dagger G_2)^{-1} \approx \frac{1}{m} G_1^\dagger G_1$$

(47)

This allows us to conclude that up to a normalizing factor, the Jacobi model approaches the Rayleigh model. The discussion above provides an “intuitive” proof, using the law of large numbers, to the fact that the Wishart ensemble approaches the Jacobi ensemble as $m \rightarrow \infty$. However, this result can be proved rigorously and is well known in random matrix theory. The proof is based on the following. For a weight function $w(x)$ and an interval $[a, b]$, orthogonal polynomials satisfy the relationship $\int_a^b p_j(x)p_i(x)w(x)dx = \delta_{ji}$. The Laguerre polynomials are orthogonal with respect to the weight function $x^k e^{-x}$ and interval $[0, \infty)$; the Jacobi polynomials are orthogonal with respect to the weight function $(1 - x)^{k_1}(1 + x)^{k_2}$ and interval $(-1, 1)$ [27], [35]. Now, the joint eigenvalue densities of the Wishart and Jacobi ensembles are proportional to $\prod_i w(\lambda_i) \prod_{i < j} |\lambda_i - \lambda_j|^2$, where $w(x)$ are the weight functions related to the Laguerre and (shifted) Jacobi polynomials, respectively. By taking the limit $k_1 \rightarrow \infty$ after scaling $x$ by $1/k_1$, it can be shown that the (shifted) Jacobi polynomials approach the Laguerre polynomials, which further proves above conclusion.

Now, the issue of the normalizing constant in (47) and (48), $1/m$, should be further explained. With fixed $m_t, m_r$, increasing $m$ has two effects. One effect is power loss into the unaddressed modes. This effect is actually pretty strong, so that for a fixed $\rho$, the channel matrix, the received SNR, and hence the capacity vanish with $m$. The other effect is that with increasing $m$, the channel matrix becomes more “random,” e.g., the matrix elements becomes statistically independent, and so the model is closer to the Rayleigh model. To compare the Jacobi model to the Rayleigh mode, we need to compensate for the power loss with increasing $m$, and concentrate only on the “randomness” effect. For this, we evaluate the channel characteristics (capacity, outage probability) in terms of $\tilde{\rho}$, the average SNR at each receive mode, given by

$$\tilde{\rho} = \frac{\rho}{m_r}E[H_{11}] = \frac{\rho}{m_r}E \sum_{i=1}^{m_t} \lambda_i$$

(49)

In the Rayleigh channel, $H_{11}$ is Gaussian; thus, $\tilde{\rho} = \rho m_t$. For the Jacobi channel, $\tilde{\rho}$ can be evaluated by applying the marginal PDF $f_{\lambda_i}(\lambda_i)$ of the channel’s singular values. This PDF is computed in Appendix A. Nonetheless, for $m \gg m_t, m_r$, we can apply (47) and (48) to have $\tilde{\rho} \approx \rho m_t/m_r$.

Following that, in Fig. 7, we compare the Rayleigh and Jacobi models, for $m_t = m_r = 2$. As $m$ increases, the Jacobi model approaches the Rayleigh model in terms of the ergodic capacity and outage probability, as a function of $\tilde{\rho}$. For example, with this normalization, the difference between the ergodic capacities of the Rayleigh and Jacobi models is less than 0.1 dB already for $m \geq 32$.

VIII. DISCUSSION

The Jacobi MIMO channel is defined by the transfer matrix $H_{11}$, a truncated $m_r \times m_t$ portion of an $m \times m$ Haar-distributed unitary matrix. By establishing the relation between the channel’s singular values and the Jacobi ensemble of random matrices, we derived the ergodic capacity, outage probability,
and optimal DMT. An interesting phenomenon is observed when the parameters of the model satisfy \( m_t + m_r > m \): for any realization of \( \mathbf{H}_{11} \), \( m_t + m_r - m \) singular values are 1. This results in an ergodic capacity which is at least \( m_t + m_r - m \) times the SISO capacity. In the nonergodic scenario, this enables a strictly zero-outage probability and an exponentially decaying error probability ("infinite diversity") for any transmission rate below \( m_t + m_r - m \).

In this study, we considered the case where the full \( \mathbf{H} \)-matrix is drawn according to Haar measure on the group of all \( m \times m \) unitary matrices. This \( \mathbf{H} \) belongs to what is known in random matrix theory as circular unitary ensemble (CUE). The eigenvalues of \( \mathbf{H}_{11}^{\dagger} \mathbf{H}_{11} \) then correspond to Jacobi unitary ensemble. It is known that, depending on certain symmetries of the system to be modeled, one can have other kind of ensembles of unitary matrices also, for example, circular orthogonal ensemble (COE). In this case, the ensemble comprises of unitary matrices which are symmetric, and then, the eigenvalues of \( \mathbf{H}_{11}^{\dagger} \mathbf{H}_{11} \) correspond to Jacobi orthogonal ensemble (JOE). Since the marginal density in this case is known, it can be used, as was done in this study, to calculate the ergodic capacity, outage probability, and DMT of the induced fading model. Furthermore, just as the Rayleigh model is obtained in the limit \( m \gg m_t, m_r \) when \( \mathbf{H} \) is taken from CUE, one-sided Gaussian model will follow if \( \mathbf{H} \) is taken from COE. Thus, it will be interesting to find communication media with "reciprocity" or symmetry feature that can be naturally modeled by the JOE.

The main motivation to define the Jacobi model comes from optical communication. Nonetheless, the results presented in this paper may provide conceptual insights on fading channels in other communication scenarios. The size of the unitary matrix, \( m \), can be viewed as the number of orthogonal propagation paths in the medium, whereas \( m_t \) and \( m_r \) are the number of addressed paths at the transmitter and receiver, respectively. The Jacobi fading model can be regarded as providing statistical model for the structure of the power loss in a system, where for fixed \( m_t \) and \( m_r \), the size of the unitary matrix \( m \) defines the "fading measure" of the channel. For example, when \( m \) is equal to \( m_r \), the transfer matrix \( \mathbf{H}_{11} \) is simply composed of orthonormal columns: its elements (i.e., the path gains) are highly dependent and there is no randomness in the received power. As \( m \) becomes greater, the orthogonality of the columns and rows of \( \mathbf{H}_{11} \) fades, the dependence between the path gains becomes weaker, and the power loss in the unaddressed receive outputs increases. Indeed, when \( m \) is very large with respect to \( m_t \) and \( m_r \), with proper normalization that compensates for the average power loss, the Jacobi fading model approaches to the Rayleigh model. The Jacobi model, thus, introduces new concepts in fading channels, providing a degree of freedom to scale the model from a unitary channel up to the Rayleigh channel.

**APPENDIX A**

**PROOF OF THEOREM 1**

The Gaudin–Mehta method [28] is used here for proving Theorem 1. According to (10), the ergodic capacity satisfies

\[
C(m_t, m_r, m; \rho) = E[\log \det(1 + \rho \mathbf{H}_{11} \mathbf{H}_{11}^\dagger)]
\]

(50)

\[
= E\left[ \sum_{\lambda_i} \log(1 + \lambda_i \rho) \right]
\]

(51)

where \( \{\lambda_i\}_{i=1}^n \) are the eigenvalues of \( \mathbf{H}_{11} \). To simplify notations, let us assume \( m_t \leq m_r \) (one can simply replace \( m_t \) with \( m_r \) to obtain the proof for \( m_t > m_r \)). Thus, we can write

\[
C(m_t, m_r, m; \rho) = m_t E[\log(1 + \rho \lambda_1)].
\]

(52)

Now, the joint distribution of the ordered eigenvalues \( f\lambda(\lambda_1, \ldots, \lambda_{m_r}) \) is given by (3). The joint distribution of the unordered eigenvalues equals

\[
\frac{1}{m!} f\lambda(\lambda_1, \ldots, \lambda_{m_r}).
\]

Thus, we can compute the density of \( \lambda_1 \) by integrating out \( \{\lambda_i\}_{i=2}^{m_r} \), that is

\[
f\lambda_1(\lambda_1) = \int_0^1 \cdots \int_0^1 \frac{1}{m!} f\lambda(\lambda_1, \ldots, \lambda_{m_r}) \prod_{i=2}^{m_r} d\lambda_i.
\]

(53)

By taking

\[
\lambda_1 = \frac{1}{2}(1 - \lambda);
\]

(54)

we can write

\[
f\lambda_1(\lambda_1) = \int_0^1 \cdots \int_0^1 f\lambda_1(\lambda_1, \ldots, \lambda_{m_r}) \prod_{i=2}^{m_r} d\lambda_i
\]

(55)

where

\[
f\lambda_1(\lambda_1, \ldots, \lambda_{m_r}) = K_{m_t, m_r, m}^{-1} \prod_{i=1}^{m_r} (1 - \lambda_i)^{\alpha}(1 + \lambda_i)^{\beta} \prod_{i<j} (\lambda_i - \lambda_j)^2
\]

(56)

and \( \alpha = m_r - m_t, \beta = m - m_r - m_t \). Now, the term

\[
\prod_{1 \leq i < j \leq m_r} (\lambda_i - \lambda_j)
\]

is the determinant of the Vandermonde matrix

\[
\begin{bmatrix}
1 & \ldots & 1 \\
\lambda_1 & \ldots & \lambda_{m_t} \\
\vdots & \ddots & \vdots \\
\lambda_{m_r-1}^{m_r-1} & \ldots & \lambda_{m_r-1}^{m_r-1}
\end{bmatrix}
\]

(57)

With row operations, we can transform (57) into the following matrix:

\[
\begin{bmatrix}
P_0^{(\alpha, \beta)}(\lambda_1) & \cdots & P_0^{(\alpha, \beta)}(\lambda_{m_r}) \\
\vdots & \ddots & \vdots \\
P_{m_t-1}^{(\alpha, \beta)}(\lambda_1) & \cdots & P_{m_t-1}^{(\alpha, \beta)}(\lambda_{m_r})
\end{bmatrix}
\]

(58)

where \( P_n^{(\alpha, \beta)}(x) \) are the Jacobi polynomials [27, 8.96]. These polynomials form a complete orthogonal system in the interval
\[ [-1, 1] \text{ with respect to the weighting function } w(x) = (1 - x)^\alpha (1 + x)^\beta, \text{ that is,} \]
\[ \int_1^1 w(x) p^{(\alpha, \beta)}_n(x) p^{(\alpha, \beta)}_k(x) dx = a_{k, \alpha, \beta} \delta_{kn} \]
where the coefficients \( a_{k, \alpha, \beta} \) are given by
\[ a_{k, \alpha, \beta} = \frac{2k + \alpha + \beta + 1}{2k + \alpha + \beta} \left( \frac{2k + \alpha + \beta}{k + \alpha} \right) \]

Thus, we can write
\[ \prod_{1 \leq i < j \leq m} (\hat{\lambda}_i - \hat{\lambda}_j)^{-1} \]
with respect to the weighting function
\[ C_{m_1, m_2, \ldots, m_r} \sum_{\sigma \in S_{m_1}} (-1)^{\text{sgn}(\sigma)} \prod_{i=1}^{m_r} p^{(\alpha, \beta)}_{\sigma(i)-1}(\hat{\lambda}_i) \]

where \( S_{m_1} \) is the set of all permutations of \( \{1, \ldots, m_r\} \), \( \text{sgn}(\sigma) \) denotes the signature of the permutation \( \sigma \), and \( C_{m_1, m_2, \ldots, m_r} \) is a constant picked up from the row operations on the Vandermonde matrix. We apply (61) into (56) to get (62), shown at the bottom of the page. By further integrating over \( \{\hat{\lambda}_i\}_{i=1}^{m_r} \) and applying (59), we get (64). This, however, implies that \( \sigma_1(i) = \sigma_2(i) \) for all \( i \), which results (65). Using (59) and the fact that \( f_{\lambda_i}(\hat{\lambda}_i) \) must integrate to unity, we then have
\[ f_{\lambda_i}(\hat{\lambda}_i) = \frac{1}{m_r} \sum_{k=0}^{m_r-1} \frac{|p^{(\alpha, \beta)}_{\sigma(i)-1}\hat{\lambda}_i|^2}{k+k=\alpha+\beta}(1-\hat{\lambda}_i)^\alpha(1+\hat{\lambda}_i)^\beta. \]

Turning back to \( \lambda_i \), we get
\[ f_{\lambda_i}(\lambda_i) = \frac{1}{m_r} \sum_{k=0}^{m_r-1} \frac{|p^{(\alpha, \beta)}_{\sigma(i)-1}\lambda_i|^2}{k+k=\alpha+\beta}(1-\lambda_i)^\alpha(1+\lambda_i)^\beta \]
where
\[ C_{m_1, m_2, \ldots, m_r} \sum_{\sigma_1, \sigma_2 \in S_{m_1}} (-1)^{\text{sgn}(\sigma_1) + \text{sgn}(\sigma_2)} \prod_{i=1}^{m_r} (1 - \lambda_i)^\alpha(1 + \lambda_i)^\beta p^{(\alpha, \beta)}_{\sigma_1(i)-1}(\lambda_i) p^{(\alpha, \beta)}_{\sigma_2(i)-1}(\lambda_i) \]

APPENDIX B
PROOF OF THEOREM 4
The outage probability for a transmission rate \( R \) is
\[ P_{\text{out}}(m_1, m_r, m_r; R) = \inf_{Q_1, Q_2} P_r \left[ \log \det(1_{m_r} + \rho H_{11} HQ_{11}^\dagger) < R \right] \]
where the minimization is over all covariance matrices \( Q \) of the transmitted signal that satisfy the power constraints. As was already mentioned, since the statistics of \( H_{11} \) is invariant under unitary permutations, the optimal choice of \( Q \), when applying constant per-mode power constraint, is simply the identity matrix. When imposing power constraint on the total power over all modes, we can take \( Q = 1_{m_r} \) if \( \rho \gg 1 \) since
\[ P_{\text{out}}(m_r, m_r, m_r; R) = P_r \left[ \log \det(1_{m_r} + \rho H_{11} H_{11}^\dagger) < R \right] \]
where we use \( \lim \) to denote exponential equality, i.e., \( f(\rho) = \rho^d \) denotes
\[ \lim_{\rho \rightarrow \infty} \frac{\log f(\rho)}{\log \rho} = d. \]

Equation (70) can be proved by picking \( Q = 1_{m_r} \) to derive an upper bound on the outage probability and \( Q = m_r 1_{m_r} \) to derive a lower bound. It can be easily shown that these bounds are exponentially tight (see [29]); hence, in the scale of interest, we can take \( Q = 1_{m_r} \).

Now, let the transmission rate be \( R = r \log(1+\rho) \), and without loss of generality, let us assume that \( m_r \leq m_r \) (the outage probability is symmetric in \( m_r \) and \( m_r \)). Since
\[ \log \det(1_{m_r} + \rho H_{11} H_{11}^\dagger) = \log \det(1_{m_r} + \rho H_{11} H_{11}^\dagger) \]
we can apply the joint distribution of the ordered eigenvalues of \( H_{11}^\dagger H_{11} \) to write
\[ P_{\text{out}}(m_r, m_r, m_r; r \log(1+\rho)) \leq K_{m_r}^{-1} \int_{B} \prod_{i=1}^{m_r} \lambda_i^{1/2} \prod_{i<j}(\lambda_i - \lambda_j)^2 \ d\mathbf{A} \]

\[ f_{\lambda_1, \ldots, \lambda_{m_r}}(\hat{\lambda}_1, \ldots, \hat{\lambda}_{m_r}) - C_{m_1, m_2, \ldots, m_r} \sum_{\sigma_1, \sigma_2 \in S_{m_1}} (-1)^{\text{sgn}(\sigma_1) + \text{sgn}(\sigma_2)} \prod_{i=1}^{m_r} (1 - \hat{\lambda}_i)^\alpha(1 + \hat{\lambda}_i)^\beta p^{(\alpha, \beta)}_{\sigma_1(i)-1}(\hat{\lambda}_i) p^{(\alpha, \beta)}_{\sigma_2(i)-1}(\hat{\lambda}_i) \]

\[ f_{\lambda_1}(\hat{\lambda}_1) = \int_1^1 \cdots \int_1^1 f_{\lambda_1}(\hat{\lambda}_1, \ldots, \hat{\lambda}_{m_r}) \prod_{i=1}^{m_r} d\hat{\lambda}_i \]

\[ = C_{m_1, m_2, \ldots, m_r} \sum_{\sigma_1, \sigma_2 \in S_{m_1}} (-1)^{\text{sgn}(\sigma_1) + \text{sgn}(\sigma_2)} (1 - \hat{\lambda}_i)^\alpha(1 + \hat{\lambda}_i)^\beta p^{(\alpha, \beta)}_{\sigma_1(i)-1}(\hat{\lambda}_i) p^{(\alpha, \beta)}_{\sigma_2(i)-1}(\hat{\lambda}_i) \prod_{i=2}^{m_r} a_{\sigma_1(i)\sigma_2(i)\delta_{\sigma_1(i)\sigma_2(i)}} \]

\[ = C_{m_1, m_2, \ldots, m_r}(m_r - 1)! \sum_{k=0}^{m_r-1} (1 - \hat{\lambda}_i)^\alpha(1 + \hat{\lambda}_i)^\beta [p^{(\alpha, \beta)}_{k}(\hat{\lambda}_i)]^2 \prod_{i \neq k} a_{\sigma_1(i)\sigma_2(i)\delta_{\sigma_1(i)\sigma_2(i)}} \]
where \( \beta_1 = m_r - m_t, \beta_2 = m - m_r - m_t, K_{m,r,m} \) is a normalizing factor, and

\[
B = \{ \alpha : \prod_{i=1}^{m_t} (1 + \rho \lambda_i) < (1 + \rho)^{m_t} \}
\]

is the set of \( 0 \leq \lambda_1 \leq \cdots \leq \lambda_{m_t} \leq 1 \) that describes the outage event. Letting \( m_t = m \) allows us to write

\[
\text{P}_{\text{out}}(m_r, m_r, r \log (1 + \rho)) \geq \int_B \prod_{i=1}^{m_t} \rho^{-\alpha_i (\beta_i + 1)} (1 - \rho^{-\alpha_i})^{\beta_2} \prod_{i < j} (\rho^{-\alpha_i} - \rho^{-\alpha_j})^2 d\alpha.
\]

Since

\[
1 + \rho^{1 - \alpha_i} = \rho^{(1 - \alpha_i)^{+}}
\]

where \((x)^+ = \max\{0, x\}\), we can describe the set of outage events by

\[
B = \{ \alpha : \alpha_1 \geq \cdots \geq \alpha_{m_t} \geq 0, \sum_{i=1}^{m_t} (1 - \alpha_i)^{+} < r \}.
\]

Now, the term \((\log \rho)^{m_t} K_{m_t,m_t,m}^{-1}\) satisfies

\[
\lim_{\rho \to \infty} \frac{\log((\log \rho)^{m_t} K_{m_t,m_t,m}^{-1})}{\log \rho} = 0.
\]

Thus, we can write

\[
\text{P}_{\text{out}}(m_r, m_r, r \log (1 + \rho)) \geq \int_B \prod_{i=1}^{m_t} \rho^{-\alpha_i (\beta_i + 1)} (1 - \rho^{-\alpha_i})^{\beta_2} \prod_{i < j} (\rho^{-\alpha_i} - \rho^{-\alpha_j})^2 d\alpha.
\]

In [29, Th. 4], it was shown that the right-hand side of above satisfies

\[
\int_B \prod_{i=1}^{m_t} \rho^{\alpha_i (\beta_i + 1)} \prod_{i < j} (\rho^{\alpha_i} - \rho^{\alpha_j})^2 d\alpha \geq \rho f(\alpha^*)
\]

where

\[
f(\alpha) = \sum_{i=1}^{m_t} (2i - 1 + m_r - m_t) \alpha_i,
\]

and

\[
\alpha^* = \arg \inf_{\alpha \in B} f(\alpha).

Ronen Dar received the B.Sc. (cum laude) and M.Sc. (summa cum laude) degrees in electrical engineering from the Tel-Aviv University, Israel, in 2008 and 2011, respectively. He is currently pursuing a Ph.D. degree in electrical engineering at Tel-Aviv University.

Mr. Dar served as an Algorithm engineer in several hi-tech companies, including Intel’s mobile wireless group and Anobit Technologies, a developer of advanced signal processing technologies for the storage markets. He is the co-author of several patents in the fields of communication and signal processing.

Meir Feder (S‘81–M‘87–SM‘93–F‘99) received the B.Sc. and M.Sc. degrees from Tel-Aviv University, Israel and the Sc.D. degree from the Massachusetts Institute of Technology (MIT) Cambridge, and the Woods Hole Oceanographic Institution, Woods Hole, MA, all in electrical engineering in 1980, 1984 and 1987, respectively.

After being a research associate and lecturer in MIT he joined the Department of Electrical Engineering—Systems, School of Electrical Engineering, Tel-Aviv University, where he is now a Professor, head of the school and the incumbent of the Information Theory Chair. He has visiting appointments at the Woods Hole Oceanographic Institution, Scripps Institute, Bell laboratories and has been a visiting professor at MIT. He is also extensively involved in the high-tech industry as an entrepreneur and angel investor. He co-founded several companies including Peach Networks, a developer of a server-based interactive TV solution which was acquired by Microsoft, and Amimon a provider of ASIC’s for wireless high-definition A/V connectivity at home.

Prof. Feder is a co-recipient of the 1993 IEEE Information Theory Best Paper Award. He also received the 1978 “creative thinking” award of the Israeli Defense Forces, the 1994 Tel-Aviv University prize for Excellent Young Scientists, the 1995 Research Prize of the Israeli Electronic Industry, and the research prize in applied electronics of the Ex-Serviceman Association, London, awarded by Ben-Gurion University.

Mark Shtaif received his M.Sc. and Ph.D. degrees in electrical engineering at the Technion in 1993 and 1997, respectively.

In 1997 he joined the Light-wave Networks Research Department at AT&T Labs Research as Senior and then Principal Member of Technical Staff. At AT&T his work centered on modeling and characterization of optical fiber communication systems focusing on propagation effects in optical fibers including fiber non-linearities, polarization mode dispersion, special modulation formats and interaction of signals and noise. During his employment he consulted to the AT&T business units on the integration of fiber-optic technologies. In 2000 he became a Principal Architect in Celion Networks, an optical networking company, where he worked on the analysis and design of long-haul optical transmission systems. In April 2002 he joined the School of Electrical Engineering at Tel-Aviv University, where he is teaching and conducting research in areas related to fiber-optics and optical communications. Prof. Shtaif is a fellow of the Optical Society of America (OSA).
