ABSTRACT

The Large Area Telescope on board the Fermi satellite observed a gamma-ray flare in the Crab Nebula lasting for approximately nine days in April of 2011. The source, which at optical wavelengths has a size of $\approx 11$ lt-yr across, doubled its gamma-ray flux within eight hours. The peak photon flux was $(186 \pm 6) \times 10^{-7}$ cm$^{-2}$ s$^{-1}$ above 100 MeV, which corresponds to a 30-fold increase compared to the average value. During the flare, a new component emerged in the spectral energy distribution, which peaked at an energy of $(375 \pm 26)$ MeV at flare maximum. The observations imply that the emission region was likely relativistically beamed toward us and that variations in its motion are responsible for the observed spectral variability.

Key words: gamma rays: stars – ISM: supernova remnants – magnetic reconnection – magnetohydrodynamics (MHD) – pulsars: individual (Crab) – radiation mechanisms: non-thermal

1. INTRODUCTION

The Crab Nebula is the remnant of a supernova observed in 1054 AD. The explosion left behind a rotating neutron star emitting electromagnetic radiation pulsed at the rotation period, which powers a wind of relativistic particles. These particles interact with the remnant gas and magnetic field, causing the nebula to glow bright at all wavelengths, predominantly by synchrotron radiation. The spectral energy distribution (SED) of the nebula is, accordingly, dominated by a synchrotron component extending from radio wavelengths into the gamma-ray band (Hester 2008). Above 450 MeV a second component emerges, attributed to inverse-Compton scattering by the same relativistic particles (Gould 1965; de Jager & Harding 1992; Atoyan et al. 1996). The angular size of the Crab Nebula is $\approx 0.1 \, ^{\circ}$ in the optical and smaller at higher energies. This corresponds to 3.5 pc, or 11 lt-yr, at its estimated distance of 2 kpc (Trimble 1973).

Today, the pulsar and nebula (henceforward referred to together as the Crab) are considered prime examples of non-thermal sources in the universe and serve as a laboratory for relativistic plasma physics. New puzzles for our understanding of the Crab have been posed by the detection of three bright gamma-ray flares by the AGILE satellite and the Large Area Telescope (LAT) on board the Fermi satellite between 2007 and 2010 (Abdo et al. 2011a; Tavani et al. 2011). During these flares the unpulsed component of the gamma-ray flux increased by a factor of $\approx 10$ on timescales as short as 12 hr (Balbo et al. 2011), while the period and flux of the pulsed component remained stable.

More recently, in April of 2011 the LAT detected a fourth flare, three times brighter than any of the previous ones (Buehler et al. 2011; Hays et al. 2011). The flare was swiftly confirmed by the AGILE satellite (Striani et al. 2011). Observations at lower energies, in particular by the Chandra X-Ray Observatory, have not yet revealed any variability correlated with the gamma-ray flares (Tennant et al. 2011). However, analysis of these observations is ongoing and will be discussed elsewhere. Here we present the LAT gamma-ray results obtained during the flare, together with a broader analysis of the first 35 months of Crab observations by Fermi.

2. THE LARGE AREA TELESCOPE AND DATA ANALYSIS

The LAT is a pair-conversion telescope, sensitive to gamma rays with energies greater than 20 MeV. It has a large field of view ($\approx 2.4 \, ^{\circ}$) and images the full sky every three hours. The angular resolution of the LAT varies with photon energy. The 68% containment radius ranges from approximately 6$^{\circ}$ at 70 MeV to 0.2 above 10 GeV (Atwood et al. 2009). LAT scientific observations began in 2008 August. We analyzed data taken within 20$^{\circ}$ of the Crab in the first 35 months of observations (MJD 54683–55728). The average spectral properties of the Crab were derived from the first 33 months...
Fluxes and spectra were obtained by maximizing the likelihood of source models using unbinned gtlike from the Fermi Science Tools 9-23-01. The models included all sources in the second LAT source catalog within 20° of the Crab position (Abdo et al. 2011c) plus models for the Galactic and isotropic diffuse emission (gal_2yearp7v6_v0, iso_p7v6source). The parameters left free to vary in the likelihood fit for 33 month average spectra were the spectral parameters of the Crab, the normalization of the diffuse components, and a power-law spectral index for scaling the Galactic diffuse emission model. For analysis on shorter timescales, only the isotropic diffuse normalization was varied along with the Crab spectral properties. All other parameters were fixed to the 33 month average maximum likelihood values. The Sun was included in the source model when it was within 20° of the Crab position. The solar spectra during the two passages in front of the Crab were taken from Abdo et al. (2011b). The Moon was not included in the source model as its gamma-ray contamination was found to be negligible for observations presented here.

We used the P7_V6_SOURCE instrument response functions without in-flight point-spread function corrections, selecting photon events between 70 MeV and 300 GeV. Compared to the more typical 100 MeV threshold, this choice leads to additional systematic errors due to increased dispersion in the photon energy reconstruction. The overall systematic flux error is energy dependent: it amounts to 30% at 70 MeV and decreases to 10% above 10 GeV (Rando et al. 2011). The dominant part of this systematic error is related to the overall flux normalization. It is caused by uncertainties in the effective area determination and of the overall normalization of energy scale.

The stability of the LAT instrument over time was tested for all timescales addressed in this paper using the Vela and Geminga pulsars, which are found to be stable in flux (Abdo et al. 2010b, 2010c). Their flux variations were <10%, yielding an upper limit on the variations of the systematic errors with time. A more detailed study of the systematic uncertainties is currently being prepared within the LAT collaboration for publication.

The pulsar phase was assigned to the detected gamma rays based on a high-time-resolution pulsar ephemeris. To obtain the latter, we extracted 400 pulsar times of arrival (TOAs) from LAT photons collected from MJD 54684 to 55668 with a typical uncertainty of ~100 μs (Ray et al. 2011). Using tempop2 (Hobbs et al. 2006), we fitted a timing solution to these TOAs with a typical residual of 108 μs, or about 3 × 10^-3 of the pulsar period. To obtain these white residuals, we modeled the pulsar timing noise using the method of Hobbs et al. (2004), with 20 harmonically related sinusoidal terms. The ephemeris parameter file, and the light curves and spectra shown in this paper are publicly available online.14

3. TIME-AVERAGE ENERGY SPECTRA

The Crab appears to the LAT as a point source, even at the highest photon energies. To separate nebular gamma-ray emission from that of the pulsar we apply a cut on the pulsar phase. The phased count rate of the pulsar with its double-peaked structure is shown in Figure 1. The pulsar dominates the phase-averaged gamma-ray flux, but its flux in the off-pulse interval from 0.56 to 0.88 is negligible (Abdo et al. 2010a). It is in this interval that we measure the properties of the nebula.

The LAT detects the nebula in the energy range between the high-energy end of the synchrotron and the low-energy end of the inverse-Compton components of the SED. The average nebular spectrum measured during the first 33 months of Fermi observations is shown in Figure 2. We fitted it as the sum of synchrotron and inverse-Compton components. The differential photon spectrum, Φ(E), of the synchrotron component was parameterized with a power law

\[ Φ_S(E) = \frac{F_S}{(100\text{ MeV})^{1-\gamma_S}} E^{-\gamma_S}, \]  

14 http://www-glast.stanford.edu/pub_data/691/
with an integral photon flux above 100 MeV of $F_\gamma = (6.1 \pm 0.2) \times 10^{-7}$ cm$^{-2}$ s$^{-1}$ and a soft photon index of $\gamma_S = 3.59 \pm 0.07$.

The spectrum of the inverse-Compton component softens significantly with respect to a power law at higher energies, as expected from measurements at very high energy (VHE) gamma rays (Aharonian et al. 2006; Zanin et al. 2011; Abdo et al. 2010a). The spectrum was parameterized by a smoothly broken power law with a curvature index of $\beta = 0.2$:

$$\Phi_\gamma(E) = \Phi_{\gamma,0} \left( \frac{E}{100 \text{ MeV}} \right)^{-\gamma_{1,1}} \left( 1 + \left( \frac{E}{E_b} \right)^{\gamma_{1,2}-\gamma_{1,1}} \right)^{-\beta}.$$  \hspace{1cm} (2)

The spectrum has a photon index of $\gamma_{1,1} = 1.48 \pm 0.07$ at low energies and softens to $\gamma_{1,2} = 2.19 \pm 0.17$ above a break energy of $E_b = (13.9 \pm 5.8)$ GeV. The flux normalization is $\Phi_{\gamma,0} = (5.6 \pm 1.4) \times 10^{-10}$ cm$^{-2}$ s$^{-1}$ MeV$^{-1}$ and the integral flux above 100 MeV is $F_\gamma = (1.1 \pm 0.1) \times 10^{-7}$ cm$^{-2}$ s$^{-1}$.

The averaged pulsar spectrum in the first 33 months of observations was measured in the on-pulse after accounting for the nebula emission. We parameterized the pulsar spectrum with a power-law function with a super-exponential cutoff

$$\Phi_P(E) = \Phi_{P,0} \left( \frac{E}{1 \text{ GeV}} \right)^{-\gamma_P} e^{-\left( \frac{E}{\gamma_P} \right)^{\beta}}.$$  \hspace{1cm} (3)

The best-fit value for the spectral index is $\gamma_P = 1.59 \pm 0.01$, for the break energy $E_{P,c} = (504 \pm 63)$ MeV and for the curvature index $\kappa = 0.43 \pm 0.01$. The normalization is given by $\Phi_{P,0} = (8.1 \pm 0.5) \times 10^{-10}$ cm$^{-2}$ s$^{-1}$ MeV$^{-1}$. The integral flux above 100 MeV is $F_P = (20.4 \pm 0.1) \times 10^{-7}$ cm$^{-2}$ s$^{-1}$, in agreement with the value measured after eight months of observations (Abdo et al. 2010a).

The pulsed emission from the Crab has recently been detected between $\approx 25$–400 GeV. This emission is constrained to pulses which are narrower by a factor of approximately two compared to the LAT energy range. Pulsed emission at these energies challenges current pulsar models (Aliu et al. 2008, 2011; Aleksic et al. 2011). A more detailed spectral analysis of the Crab pulsar in the Fermi-LAT energy range and its connection to the pulsar VHE emission is currently being performed and will be published elsewhere.

4. TEMPORAL FLUX VARIATIONS

In order to probe the flux variation over time, the flux from the Crab was evaluated in 12 hr time intervals. The combined pulsar and nebular spectrum was modeled as a power law in energy, as further spectral features are not resolvable on these short timescales for typical observed fluxes.

The resulting light curve is shown in Figure 3, where the three flares previously reported by the Fermi-LAT collaboration are indicated. Variability is seen over the whole 35 month period. This is also apparent in the Fourier power density spectrum (PDS) shown in Figure 4, which is approximately described by a power law with a spectral index of $\approx 0.9$. The PDS was derived using the fast Fourier transform for evenly spaced data, interpolating over the short time interval MJD 54901–54906, during which the Crab was not observed by Fermi. We verified that results are essentially indistinguishable from power spectra computed using the techniques for unevenly sampled time series described later in this section. The PDS shows significant power above the noise level on timescales from years to weeks.

Variations on these timescales are also present outside of the flaring periods. This can be seen in the PDS of the time interval MJD 54884–55457 also shown in Figure 4, where the nebula did not show large variations in flux. The spectral index of the PDS during this time is approximately 1.0.

There are compelling reasons to believe that the phase-averaged Crab pulsar and the inverse-Compton component flux are constant in the LAT energy range (de Jager & Harding 1992; Atoyan et al. 1996), or at least that they vary only very slowly as the pulsar spins down, and that any rapid variability is attributable to the synchrotron component of the nebula. This was confirmed observationally on monthly timescales for the first 24 months of Fermi observations (Abdo et al. 2011a). To test this assumption on the 12 hr timescales studied here, we measured the flux in the on-pulse interval, subtracting the nebula flux measured in the off-pulse interval for each time bin. The pulsar flux was found to be stable within 20%. No significant variations were found. The inverse-Compton component of the nebula is too faint to be consistently detected in 12 hr time windows. Therefore, the variability of this component cannot be quantified from our analysis on these timescales. However, significant flux variations of the inverse-Compton component on short timescales are strongly disfavored theoretically. The observed absence of variations on monthly timescales is consistent with constancy on the shorter scales of interest here.

On 2011 April 9 the flux of the Crab increased dramatically. Once the source reached flux levels comparable to the 2009 and 2010 flares the Fermi satellite was commanded to switch to a pointed observation targeting the Crab (MJD 55663.70–55671.02). In this mode the exposure toward the source increased by a factor of about four compared to the standard all-sky monitoring. During these observations the Crab erupted to a peak flux of $(186 \pm 6) \times 10^{-7}$ cm$^{-2}$ s$^{-1}$ above 100 MeV during the 12 hr period centered at MJD 55667.14, as shown in Figure 3. This corresponds to a flux increase of a factor seven compared to the average total flux from the Crab and a factor of 30 compared to the flux from the nebula. We verified that the flare is indeed positionally coincident with the Crab Nebula, with a best-fit localization of R.A. = 83:65, Decl. = 21:98 (J2000), and an error radius of 0.04 at 95% confidence.

The high gamma-ray flux during the flare, combined with the increased exposure of the pointed observations allowed us to study the flux evolution down to timescales below the $\approx 1.5$ hr orbital period of Fermi. On such timescales occultation of the source by the Earth needs to be taken into account. The time binning was therefore adjusted such that only time periods during which the Crab is visible to the LAT are used. These visibility windows were further split into bins of equal exposure, yielding a mean bin duration of nine minutes. The evolution of the flux during the flare in this binning is shown in Figure 5. The flare lasted for approximately nine days and is composed of two sub-flares, peaking around MJD 55665 and MJD 55667. During both, the flux increased rapidly, reaching its maximum value within approximately one day. A second rise or “shoulder” is observed during the decaying phase of both sub-flares. Whether this is coincidental cannot be assessed on the basis of these two events alone. If these shoulders are not interpreted as additional flares of lower amplitude, the decay time is approximately 1.5 and 3 days for the first and second sub-flare, respectively.

To investigate the significance of peaks on smaller timescales in the flare light curve, we decomposed it into periods...
Figure 3. Integral flux above 100 MeV from the Crab as a function of time for the first 35 months of Fermi observations. The time binning is 12 hr. The dotted blue line indicates the sum of the 33 month average fluxes from the inverse-Compton nebula and the pulsar. The dashed blue line shows the average flux of the synchrotron nebula summed to the latter. Fluxes are shown on a log scale. The three flares detected by the Fermi LAT are indicated. A fourth flare was detected in 2007 October (MJD 54380) by AGILE (Tavani et al. 2011).

(A color version of this figure is available in the online journal.)

compatible with a constant flux. The time windows are referred to as “Bayesian Blocks” (BBs). They were determined finding the partition which maximizes the sum of the cost function assigned to each BB (Scargle 1998). The cost function was set to the logarithm of the maximum likelihood for the constant flux hypothesis. The algorithm to determine the optimal partition is described by Jackson et al. (2005). The BB-binned light curve is shown in Figure 5. It is statistically compatible with the original light curve ($\chi^2/ndf = 257/232$). This implies that flux variations within each BB cannot be distinguished with confidence from a locally constant flux. The shortest BBs are detected at the maximum of both sub-flares and have durations of $\approx 9$ hr.

In order to measure the rate of flux increase at the rising edges of the sub-flares we parameterized them with an exponential function plus a constant background. The best-fit functions are shown in Figure 5. The time ranges over which the fits were performed were defined by the centers of the BBs before and at the maximum of each sub-flare. The resulting doubling time is $4.0 \pm 1.0$ hr and $7.0 \pm 1.6$ hr for the first and second sub-flare, respectively. As these values depend on the somewhat arbitrarily chosen parameterization and fit ranges, we conservatively estimate that the doubling timescale in both sub-flares is $t_d \lesssim 8$ hr.

The PDS of the 2011 April flare is shown in Figure 4. It was obtained by computing the Fourier transform of the autocorrelation function using an algorithm for unevenly sampled data (Edelson & Krolik 1988). The PDS can be described by a power law of index $\approx 1.1$ and reaches the noise floor at a frequency of $\approx 0.6$ cycles per day. The doubling time of the corresponding
The sinusoidal component is \(\approx 10\) hr, in agreement with the expectation from the measured doubling times of the flares.

The pulsar flux remained unchanged during the flare, with an average flux above 100 MeV of \(F_P = (21.7 \pm 1.1) \times 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}\) during the main part of the flare (MJD 55663.70–55671.02). The flux increase is phase-independent. This is illustrated in Figure 1, where the phasogram during the main flare period is shown. The peaks in the on-pulse interval remain at the same position. We also searched for periodicities other than the Crab pulsar with the time-differencing technique (Atwood et al. 2006), applying the event-weighting technique described in Bickel et al. (2008). We scanned the frequency range 0.1–256 Hz, allowing for a possible spin-down up to twice the value of the Crab pulsar. No significant signal was found besides the pulsar, which was detected with a significance \(> 5.5\sigma\).

Finally, we searched for photon clumping on timescales shorter than the \(\approx 10\) min time binning by applying a Bayesian Block analysis on the single photon arrival times, with no significant detection.

### 4.1. Spectral Evolution During the Flare

In order to measure the energy spectrum during the flare, and its evolution with time, the data must be averaged in time intervals long enough to ensure adequate photon statistics, but short enough to provide adequate temporal resolution. The 11 bins of approximately constant flux, derived from the BB analysis, provide a reasonable compromise between these two constraints.

The SEDs for each of the time bins are shown in Figure 6, after subtracting the steady emission from the pulsar and the inverse-Compton component of the nebula. It can be clearly seen that a new spectral component emerges from the synchrotron nebula during the flare, moving into the *Fermi* energy range as the flare evolves. Its flux reaches a maximum between MJD 55666.997 and 55667.366 (frame 7); during this period the peak in the SED is clearly detected at \(E_{\text{peak}} = (375 \pm 26)\) MeV.
It is difficult to parameterize the spectral shape of the flaring component due to the likely contamination by background flux from the synchrotron nebula not related to the flare. The determination of the latter is degenerate with the measurement of the flare component, as only the summed flux is measured. To break this degeneracy we proceed under the following assumptions.

1. The spectrum of the synchrotron nebula during the flare can be described by a power-law function and does not vary in time.
2. The spectrum of the flaring component can be described by a power law with an exponential cutoff (Equation (3) with $\kappa = 1$). While the cutoff energy and normalization of the spectrum vary, the spectral index remains constant during the flare.

We derived the spectral index of the flaring component and the spectrum of the background synchrotron component in a composite likelihood fit to all the time windows displayed in Figure 5, simultaneously measuring the energy cutoff and flux normalization evolution of the flaring component in each of the time windows. For this we used the composite likelihood 2 part of the Fermi Science Tools.

The best-fit values for the background synchrotron nebula during the flare period are $F_S = (5.4 \pm 5.2) \times 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}$ and $\gamma_S = 3.9 \pm 1.3$, consistent with the average value measured during the first 33 months of observation. The spectral index of the flaring component is measured to be $\gamma_F = 1.27 \pm 0.12$. The best-fit values for $E_{F,c}$ and the energy flux above 100 MeV, $f_F$, are shown in Figure 7.

Figure 6. Spectral energy distribution evolution during the 2011 April Crab flare. Arrows indicate 95% confidence flux upper limits. The time windows are indicated in the bottom left corner of each panel and correspond to the ones indicated in Figure 5. The dotted line shows the SED of the flaring component, the dot-dashed line the constant background from the synchrotron nebula, and the dashed line is the sum of both components (see the text). The average Crab nebular spectrum in the first 33 months of Fermi observations is also shown in gray for comparison.

Figure 7. Total energy flux above 100 MeV, $f_F$, as a function of cutoff energy $E_c$ for the flaring component of the 2011 April flare. The values correspond to the parameterizations shown in frames 1–10 of Figure 6 (the values obtained from frame Nr 11 are not included, as no significant spectral curvature was detected in this time interval, allowing no robust determination of $E_c$). The number next to each marker denotes the corresponding frame. The axis on the right-hand side indicates the apparent luminosity in units of the pulsar spin-down power of $5 \times 10^{38} \text{ erg s}^{-1}$ (Hester 2008). The numbered solid lines indicate the slope of the corresponding power-law dependency $f_F \sim E^{\alpha}$. The dotted line marks the best-fit function in this parameterization with $\alpha = 3.42 \pm 0.86$. 
This simple parameterization yields a good description of the flare evolution, as can be seen in Figure 6. The data are therefore compatible with the interpretation that a new spectral component of a fixed spectral shape evolves during the flare. As shown in Figure 7, the cutoff energy of the flaring component varies significantly, having a statistical probability of being constant of only 0.04%. However, while $f_\gamma$ varies by more than an order of magnitude, the cutoff energy varies only by approximately a factor of two. The relationship between both quantities can be described approximately by a power-law function $f_\gamma \sim E_{\gamma,c}^{\alpha}$, with best-fit index of $\alpha = 3.42 \pm 0.86$.

5. DISCUSSION

A year after first being reported, the gamma-ray flares from the Crab remain enigmatic. Where within the nebula does the emission come from? What produces the flux variations? How were the emitting particles accelerated? How are the flares related to the variability observed on yearly and monthly timescales? Although several ideas have been proposed, no certain answers can be given today. The observations presented here give us the most precise look into the flare phenomenon to date, during the brightest outburst detected so far. We will proceed to discuss some of the implications and challenges posed by these observations.

One striking property of the Crab Nebula flares is their rapid flux variations, doubling within $t_d < 8$ hr at the rise of the 2011 April flare. Causality arguments imply that the emission region is compact, with a length $L < c t_d \approx 2.8 \times 10^{-4}$ pc. The emitted isotropic power at the peak of the flare of $\approx 4 \times 10^{36}$ erg s$^{-1}$ corresponds to $\approx 1\%$ of the total spin-down power of the pulsar, the ultimate energy source of the nebula. It is difficult to explain how this energy is focused into such a small emission volume. The focusing is generally easier to explain when the emission site is closer to the pulsar. The absence of pulsation in the flare signal implies that the emission region is at least located outside the light cylinder of the pulsar. Another possibility to explain the flare brightness is that the emission is highly anisotropic, as would be expected if the emission region moves relativistically toward us. While only mildly relativistic motion with velocities of $\approx 0.5c$ is observed inside the nebula (Scargle 1969; Hester et al. 2002; Melatos et al. 2005), relativistic motion is expected in the pulsar wind and in the downstream medium behind the wind termination (Camus et al. 2009). Relativistic bulk motion is particularly expected at the “arch shock” of the wind termination, which has been proposed as the main site of gamma-ray emission (Komissarov & Lyutikov 2011).

The flare emission is expected to result from synchrotron radiation by relativistic electrons and positrons (henceforth referred to together as electrons; Abdo et al. 2011a). A new spectral component emerges in the SED during the flare. The hard photon spectrum ($\gamma \approx 1.3$) of the flaring component implies that most of the electron energy is carried by the highest energy electrons. If the electron particle density $n(\epsilon)$ per energy at an energy $\epsilon$ is characterized by a power law $n(\epsilon) \sim \epsilon^{-p}$, then the spectral index is $p \leq 2\gamma - 1 \approx 1.6$, in a random magnetic field in which the electrons are isotropically distributed. The energy per logarithmic energy interval, which is proportional to $\epsilon^{p} \times n(\epsilon)$, is therefore rising with energy. We note that such a spectrum is also inferred for the radio emitting electrons in the Crab Nebula, and more generally in pulsar wind nebula (Gaensler & Slane 2006; Sironi & Spitkovsky 2011a). While the radio emission is produced by a different electron population than the gamma-ray flares, efficient particle acceleration appears to be a common feature in these systems.

It is an interesting question how such a hard electron spectrum is produced. Standard diffusive shock acceleration typically results in spectra with $p \gtrsim 2$ (Gallant et al. 1992; Kirk et al. 2000). Even though it has been shown that harder spectra can be produced in certain field configurations with low-level turbulence (Kirk & Heavens 1989; Summerlin & Baring 2011), these conditions are not expected at termination shocks of pulsar winds. Additionally, shock acceleration appears to be inefficient at highly oblique shocks that are representative of the pulsar wind termination discontinuity (Ellison & Double 2004; Summerlin & Baring 2011; Sironi & Spitkovsky 2011b). One alternative is that magnetic reconnection in the striped pulsar wind might accelerate particles (Lyubarsky 2003; Kirk 2004; Yuan et al. 2011; Bednarek et al. 2011). However, simulations show that reconnection behind the pulsar termination probably does not provide the required electron energies to produce gamma-ray emission (Sironi & Spitkovsky 2011a). Another interesting possibility is that acceleration is occurring directly in the electric field induced by the pulsar, as discussed by Abdo et al. (2011a).

The observation of a peak synchrotron energy of $\approx 380$ MeV is among the highest yet seen from astrophysical source today. The observation is surprising as particle acceleration in the presence of synchrotron cooling is expected to limit synchrotron emission to photon energies below $\approx 150$ MeV (Guilbert et al. 1983; de Jager et al. 1996; Komissarov & Lyutikov 2011). The following two solutions to this problem have been proposed recently in this context.

1. The electric field at the acceleration site is larger in magnitude than the magnetic field. This is generally an unstable state in plasma, as charges will short out the electric field; however, temporarily such a configuration is expected, e.g., in magnetic reconnection events. The gamma-ray emission might occur afterward, when the accelerated electrons enter a region of enhanced magnetic fields (Uzdensky et al. 2011; Cerutti et al. 2011). More detailed studies are required to assess whether such a scenario is plausible in the nebula environment and can be sustained for the duration of the flares.

2. The gamma rays are emitted in a region of bulk relativistic motion, and are therefore Doppler boosted toward the observer (Komissarov & Lyutikov 2011). For a flow moving directly toward us, a Lorentz factor $\gamma \approx 2$ is sufficient to accommodate the observed peak energy.

Variations in the Doppler boosting can naturally account for the observed flux variation (Lyutikov et al. 2011). The observed spectral evolution is compatible with such an interpretation: the energy flux of the emission varies approximately as a power of $\gamma = 3.42 \pm 0.86$ with the cutoff energy; a correlation with $\alpha \approx 3$ is indeed expected for variations produced by changes in relativistic beaming (Lind & Blandford 1985).

The flare brightness, the high frequency of the observed peak of the gamma-ray emission, and the spectral evolution during the flare all suggest the presence of relativistic beaming. We therefore conclude that, independent of the location of the emission region and the physical processes responsible for the flares, the emission region is moving relativistically toward us, and changes in its motion are likely the predominant mechanism responsible for the observed flux variations. Such a kinematic explanation does not however address the issue of how a moving.
source can be created dynamically and sustained radiatively in the face of strong losses. The Crab Nebula still has much more to teach us.

The Fermi LAT collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l’Energie Atomique and the Centre National de la Recherche Scientifique in France, the Agenzia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden. Additional support for science analysis during the operations phase is gratefully acknowledged from the Istituto Nazionale di Astrofisica in Italy and the Centre National d’Études Spatiales in France. J.D.S. is grateful for funding through the NASA Applied Information Systems Research program.
