Abstract. In this paper we introduce and study Event-Clock Nested Automata (ECNA), a formalism that combines Event Clock Automata (ECA) and Visibly Pushdown Automata (VPA). ECNA allow to express real-time properties over non-regular patterns of recursive programs. We prove that ECNA retain the closure and decidability properties of ECA and VPA being closed under Boolean operations and having a decidable language-inclusion problem. In particular, we prove that emptiness, universality, and language-inclusion for ECNA are Exptime-complete problems. As for the expressiveness, we have that ECNA properly extend any previous attempt in the literature of combining ECA and VPA.

1 Introduction

Model checking is a well-established formal-method technique to automatically check for global correctness of reactive systems [7]. In this setting, automata theory over infinite words plays a crucial role: the set of possible (potentially infinite) behaviors of the system and the set of admissible behaviors of the correctness specification can be modeled as languages accepted by automata. The verification problem of checking that a system meets its specification then reduces to testing language inclusion between two automata over infinite words.

In the last two decades, model checking of pushdown automata (PDA) has received a lot of attention [11,16,19]. PDA represent an infinite-state formalism suitable to model the control flow of typical sequential programs with nested and recursive procedure calls. Although the general problem of checking context-free properties of PDA is undecidable [15], algorithmic solutions have been proposed for interesting subclasses of context-free requirements [3,5,6,12]. A well-known approach is that of Visibly Pushdown Automata (VPA) [5,6], a subclass of PDA where the input symbols over a pushdown alphabet control the admissible operations on the stack. Precisely, the alphabet is partitioned into a set of calls, representing a procedure call and forcing a push stack-operation, a set of returns, representing a procedure return and forcing a pop stack-operation, and a set of internal actions that cannot access or modify the content of the stack. This restriction makes the class of resulting languages (visibly pushdown languages or VPL) very similar in tractability and robustness to that of regular languages [5,6]. VPL are closed under Boolean operations, and language inclusion is Exptime-complete. VPA capture all regular properties, and, additionally, allow to specify regular requirements over two kinds of non-regular patterns on input words: abstract paths and caller paths. An abstract path captures the local
computation within a procedure with the removal of subcomputations corresponding to nested procedure calls, while a caller path represents the call-stack content at a given position of the input.

Recently, many works [13,10,13,14,18] have investigated real-time extensions of PDA by combining PDA with Timed Automata (TA) [2], a model widely used to represent real-time systems. TA are finite automata augmented with a finite set of real-valued clocks, which operate over words where each symbol is paired with a real-valued timestamp (timed words). All clocks progress at the same speed and can be reset by transitions (thus, each clock keeps track of the elapsed time since the last reset). Constraints on clocks are associated with transitions to restrict the behavior of the automaton. The emptiness problem for TA is decidable and PSPACE complete [2]. However, since in TA, clocks can be reset nondeterministically and independently of each other, the resulting class of timed languages is not closed under complement and, in particular, language inclusion is undecidable [2]. As a consequence, the general verification problem (i.e., language inclusion) of formalisms combining unrestricted TA with robust subclasses of PDA such as VPA is undecidable as well. In fact, checking language inclusion for Visibly Pushdown Timed Automata (VPTA) is undecidable even in the restricted case of specifications using at most one clock [14].

Event-clock automata (ECA) [4] are an interesting subclass of TA where the explicit reset of clocks is disallowed. In ECA, clocks have a predefined association with the input alphabet symbols. Precisely, for each symbol $a$ there are two clocks: the global recorder clock, recording the time elapsed since the last occurrence of $a$, and the global predictor clock, measuring the time elapsed since the next occurrence of $a$. Hence, the clock valuations are determined only by the input timed word being independent of the automaton behavior. Such a restriction makes the resulting class of timed languages closed under Boolean operations, and in particular, language inclusion is PSPACE-complete [4].

Recently, a robust subclass of VPTA, called Event-Clock Visibly Pushdown Automata (ECVPA), has been proposed in [17], combining ECA with VPA. ECVPA are closed under Boolean operations, and language inclusion is EXPTIME-complete. However, ECVPA do not take into account the nested hierarchical structure induced by a timed word over a pushdown alphabet, namely, they do not provide any explicit mechanism to relate the use of a stack with that of event clocks.

**Our contribution.** In this paper, we introduce an extension of ECVPA, called Event-Clock Nested Automata (ECNA) that, differently from ECVPA, allows to relate the use of event clocks and the use of the stack. To this end, we add for each input symbol $a$ three additional event clocks: the abstract recorder clock (resp., abstract predictor clock), measuring the time elapsed since the last occurrence (resp., the time for the next occurrence) of $a$ along the maximal abstract path visiting the current position; the caller clock, measuring the time elapsed since the last occurrence of $a$ along the caller path from the current position. In this way, ECNA allow to specify relevant real-time non-regular properties including:

- Local bounded-time responses such as “in the local computation of a procedure $A$, every request $p$ is followed by a response $q$ within $k$ time units”.
Bounded-time total correctness requirements such as “if the pre-condition \( p \) holds when the procedure \( A \) is invoked, then the procedure must return within \( k \) time units and \( q \) must hold upon return”.

Real-time security properties which require the inspection of the call-stack such as “a module \( A \) should be invoked only if module \( B \) belongs to the call stack and within \( k \) time units since the activation of module \( B \)”.

We show that ECNA are strictly more expressive than ECVPA and, as for ECVPA, the resulting class of languages is closed under all Boolean operations. Moreover, language inclusion and visibly model-checking of VPTA against ECNA specifications are decidable and \( \text{Exptime} \)-complete. The key step in the proposed decision procedures is a translation of ECNA into equivalent VPTA.

**Related work.** Pushdown Timed Automata (PTA) have been introduced in [10], and their emptiness problem is \( \text{Exptime} \)-complete. An extension of PTA, namely Dense-Timed Pushdown Automata (DTPA), has been studied in [1], where each symbol in the stack is equipped with a real-valued clock representing its ‘age’ (the time elapsed since the symbol has been pushed onto the stack). It has been shown in [13] that DTPA do not add expressive power and can be translated into equivalent PTA. Our proposed translation of ECNA into VPTA is inspired from the construction in [13]. In [9], an equally-expressive extension of ECVPA [17] over finite timed words, by means of a timed stack (like in DTPA), is investigated.

### 2 Preliminaries

In the following, \( \mathbb{N} \) denotes the set of natural numbers and \( \mathbb{R}_+ \) the set of non-negative real numbers. Let \( w \) be a finite or infinite word over some alphabet. By \( |w| \) we denote the length of \( w \) (we set \( |w| = \infty \) if \( w \) is infinite). For all \( i, j \in \mathbb{N} \), with \( i \leq j \), \( w_i \) is \( i \)-th letter of \( w \), while \( w[i,j] \) is the finite subword \( w_i \cdots w_j \).

An **infinite timed word** \( w \) over a finite alphabet \( \Sigma \) is an infinite word \( w = (a_0, \tau_0)(a_1, \tau_1), \ldots \) over \( \Sigma \times \mathbb{R}_+ \) (intuitively, \( \tau_i \) is the time at which \( a_i \) occurs) such that the sequence \( \tau = \tau_0, \tau_1, \ldots \) of timestamps satisfies: (1) \( \tau_i \leq \tau_{i+1} \) for all \( i \geq 0 \) (monotonicity), and (2) for all \( t \in \mathbb{R}_+ \), \( \tau_i \geq t \) for some \( i \geq 0 \) (divergence). The timed word \( w \) is also denoted by the pair \((\sigma, \tau)\), where \( \sigma \) is the untimed word \( a_0a_1 \ldots \) and \( \tau \) is the sequence of timestamps. An \( \omega \)-timed language over \( \Sigma \) is a set of infinite timed words over \( \Sigma \).

**Pushdown alphabets, abstract paths, and caller paths.** A pushdown alphabet \( \Sigma = \Sigma_{\text{call}} \cup \Sigma_{\text{ret}} \cup \Sigma_{\text{int}} \) which is partitioned into a set \( \Sigma_{\text{call}} \) of calls, a set \( \Sigma_{\text{ret}} \) of returns, and a set \( \Sigma_{\text{int}} \) of internal actions. The pushdown alphabet \( \Sigma \) induces a nested hierarchical structure in a given word over \( \Sigma \) obtained by associating to each call the corresponding matching return (if any) in a well-nested manner. Formally, the set of well-matched words is the set of finite words \( \sigma_w \) over \( \Sigma \) inductively defined by the following grammar:

\[
\sigma_w := \varepsilon \mid a \cdot \sigma_w \mid c \cdot \sigma_w \cdot r \cdot \sigma_w
\]

where \( \varepsilon \) is the empty word, \( a \in \Sigma_{\text{int}}, c \in \Sigma_{\text{call}}, \) and \( r \in \Sigma_{\text{ret}} \).
Fix an infinite word $\sigma$ over $\Sigma$. For a call position $i \geq 0$, if there is $j > i$ such that $j$ is a return position of $\sigma$ and $\sigma[j + 1, j - 1]$ is a well-matched word (note that $j$ is uniquely determined if it exists), we say that $j$ is the matching return of $i$ along $\sigma$. For a position $i \geq 0$, the abstract successor of $i$ along $\sigma$, denoted $\text{succ}(a, \sigma, i)$, is defined as follows:

- If $i$ is a call, then $\text{succ}(a, \sigma, i)$ is the matching return of $i$ if such a matching return exists; otherwise $\text{succ}(a, \sigma, i) = \perp$ ($\perp$ denotes the undefined value).

- If $i$ is not a call, then $\text{succ}(a, \sigma, i) = i + 1$ if $i + 1$ is not a return position, and $\text{succ}(a, \sigma, i) = \perp$, otherwise.

The caller of $i$ along $\sigma$, denoted $\text{succ}(c, \sigma, i)$, is instead defined as follows:

- if there exists the greatest call position $j_c < i$ such that either $\text{succ}(a, \sigma, j_c) = \perp$ or $\text{succ}(a, \sigma, j_c) > i$, then $\text{succ}(c, \sigma, i) = j_c$; otherwise, $\text{succ}(c, \sigma, i) = \perp$.

A maximal abstract path (MAP) of $\sigma$ is a maximal (finite or infinite) increasing sequence of natural numbers $\nu = i_0 < i_1 < \ldots$ such that $i_j = \text{succ}(a, \sigma, i_{j-1})$ for all $1 \leq j < |\nu|$. Note that for every position $i$ of $\sigma$, there is exactly one MAP of $\sigma$ visiting position $i$. For each $i \geq 0$, the caller path of $\sigma$ from position $i$, is the maximal (finite) decreasing sequence of natural numbers $j_0 > j_1 \ldots > j_n$ such that $j_0 = i$ and $j_{h+1} = \text{succ}(c, \sigma, j_h)$ for all $0 \leq h < n$. Note that the positions of a MAP have the same caller (if any). Intuitively, in the analysis of recursive programs, a maximal abstract path captures the local computation within a procedure removing computation fragments corresponding to nested calls, while the caller path represents the call-stack content at a given position of the input.

For instance, consider the finite untimed word $\sigma_p$ of length 10 depicted below where $\Sigma_{\text{call}} = \{c\}$, $\Sigma_{\text{ret}} = \{r\}$, and $\Sigma_{\text{int}} = \{i\}$. 

Let $\sigma$ be $\sigma_p \cdot r^\omega$. Note that 0 is the unique unmatched call position of $\sigma$: hence, the MAP visiting 0 consists of just position 0 and has no caller. The MAP visiting position 1 is the infinite sequence 1, 6, 7, 9, 10, 11, 12, 13, ... and the associated caller is position 0; the MAP visiting position 2 is the sequence 2, 3, 5 and the associated caller is position 1, and the MAP visiting position 4 consists of just position 4 whose caller path is 4, 3, 1, 0.

### 3 Event-clock nested automata

In this section, we define the formalism of Event-Clock Nested Automata (ECNA), which allow a combined used of event clocks and visible operations on the stack. To this end, we augment the standard set of event clocks [4] with a set of abstract event clocks and a set of caller event clocks whose values are determined by considering maximal abstract paths and caller paths of the given word, respectively.

In the following, we fix a pushdown alphabet $\Sigma = \Sigma_{\text{call}} \cup \Sigma_{\text{ret}} \cup \Sigma_{\text{int}}$. The set $C_\Sigma$ of event clocks associated with $\sigma$ is given by $C_\Sigma := \bigcup_{b \in \Sigma} \{x_b^a, y_b^a, x_b^r, y_b^r, x_b^i\}$. Thus, we associate with each symbol $b \in \Sigma$, five event clocks: the global recorder
clock $x_b^w$ (resp., the global predictor clock $y_b^w$) recording the time elapsed since the last occurrence of $b$ if any (resp., the time required to the next occurrence of $b$ if any); the abstract recorder clock $x_b^R$ (resp., the abstract predictor clock $y_b^R$) recording the time elapsed since the last occurrence of $b$ if any (resp., the time required to the next occurrence of $b$) along the MAP visiting the current position; and the caller (recorder) clock $x_b^g$ recording the time elapsed since the last occurrence of $b$ if any along the caller path from the current position. Let $w = (\sigma, \tau)$ be an infinite timed word over $\Sigma$ and $i \geq 0$. We denote by $\text{Pos}(a, w, i)$ the set of positions visited by the MAP of $\sigma$ associated with position $i$, and by $\text{Pos}(c, w, i)$ the set of positions visited by the caller path of $\sigma$ from position $i$.

In order to allow a uniform notation, we write $\text{Pos}(g, w, i)$ to mean the full set $\mathbb{N}$ of positions. The values of the clocks at a fixed position $i$ of the word $w$ can be deterministically determined as follows.

**Definition 1 (Deterministic clock valuations).** A clock valuation over $C_\Sigma$ is a mapping $\text{val} : C_\Sigma \mapsto \mathbb{R}_+ \cup \{\perp\}$, assigning to each event clock a value in $\mathbb{R}_+ \cup \{\perp\}$ ($\perp$ denotes the undefined value). Given an infinite timed word $w = (\sigma, \tau)$ over $\Sigma$ and a position $i$, the clock valuation $\text{val}_w^i$ over $C_\Sigma$, specifying the values of the event clocks at position $i$ along $w$, is defined as follows for each $b \in \Sigma$, where $\text{dir} \in \{g, a, c\}$ and $\text{dir}' \in \{g, a\}$:

$$\text{val}_i^w(x_b^{\text{dir}}) =\begin{cases} 
\tau_i - \tau_j & \text{if } \exists j < i : b = \sigma_j, j \in \text{Pos}(\text{dir}, w, i), \text{ and } \forall k : (j < k < i \text{ and } k \in \text{Pos}(\text{dir}, w, i)) \Rightarrow b \neq \sigma_k \\
\perp & \text{otherwise}
\end{cases}$$

$$\text{val}_i^w(y_b^{\text{dir}'}) =\begin{cases} 
\tau_j - \tau_i & \text{if } \exists j > i : b = \sigma_j, j \in \text{Pos}(\text{dir}', w, i), \text{ and } \forall k : (i < k < j \text{ and } k \in \text{Pos}(\text{dir}', w, i)) \Rightarrow b \neq \sigma_k \\
\perp & \text{otherwise}
\end{cases}$$

It is worth noting that while the values of the global clocks are obtained by considering the full set of positions in $w$, the values of the abstract clocks (resp., caller clocks) are defined with respect to the MAP visiting the current position (resp., with respect to the caller path from the current position).

For $C \subseteq C_\Sigma$ and a clock valuation $\text{val}$ over $C_\Sigma$, $\text{val}|_C$ denotes the restriction of $\text{val}$ to the set $C$. A clock constraint over $C$ is a conjunction of atomic formulas of the form $z \in I$, where $z \in C$, and $I$ is either an interval in $\mathbb{R}_+$ with bounds in $\mathbb{N} \cup \{\infty\}$, or the singleton $\{\perp\}$ (also denoted by $[\perp, \perp]$). For a clock valuation $\text{val}$ and a clock constraint $\theta$, $\text{val}$ satisfies $\theta$, written $\text{val} \models \theta$, if for each conjunct $z \in I$ of $\theta$, $\text{val}(z) \in I$. We denote by $\Phi(C)$ the set of clock constraints over $C$.

For technical convenience, we first introduce an extension of the known class of Visibly Pushdown Timed Automata (VPTA) [10-14], called nested VPTA. Nested VPTA are simply VPTA augmented with event clocks. Therefore, transitions of nested VPTA are constrained by a pair of disjoint finite sets of clocks: a finite set $C_{st}$ of standard clocks and a disjoint set $C \subseteq C_\Sigma$ of event clocks. As usual, a standard clock can be reset when a transition is taken; hence, its value at a position of an input word depends in general on the behaviour on the automaton and not only, as for event clocks, on the word.
The class of Event-Clock Nested Automata (ECNA) corresponds to the subclass of nested VPTA where the set of standard clocks \( C_{st} \) is empty.

A (standard) clock valuation over \( C_{st} \) is a mapping \( sval : C_{st} \to \mathbb{R}_+ \) (note that the undefined value \( \perp \) is not admitted). For \( t \in \mathbb{R}_+ \) and a reset set \( Res \subseteq C_{st} \), \( sval + t \) and \( sval[Res] \) denote the valuations over \( C_{st} \) defined as follows for all \( z \in C_{st} \): \( (sval + t)(z) = sval(z) + t \), and \( sval[Res](z) = 0 \) if \( z \in Res \) and \( sval[Res](z) = sval(z) \) otherwise. For \( C \subseteq C_{\Sigma} \) and a valuation \( val \) over \( C \), \( val \cup sval \) denotes the valuation over \( C_{st} \cup C \) defined in the obvious way.

**Definition 2 (Nested VPTA).** A Büchi nested VPTA over \( \Sigma = \Sigma_{call} \cup \Sigma_{int} \cup \Sigma_{rel} \) is a tuple \( \mathcal{A} = (\Sigma, Q, Q_0, D = C \cup C_{st}, I \cup \{\top\}, \Delta, F) \), where \( Q \) is a finite set of (control) states, \( Q_0 \subseteq Q \) is a set of initial states, \( C \subseteq C_{\Sigma} \) is a set of event clocks, \( C_{st} \) is a set of standard clocks disjoint from \( C_{\Sigma} \), \( I \cup \{\top\} \) is a finite stack alphabet, \( \top \notin I \) is the special stack bottom symbol, \( F \subseteq Q \) is a set of accepting states, and \( \Delta \cup \Delta_r \cup \Delta_i \) is a transition relation, where \((D = C \cup C_{st})\):

- \( \Delta_c \subseteq Q \times \Sigma_{call} \times \Phi(D) \times 2^{C_{st}} \times Q \times I \) is the set of push transitions,
- \( \Delta_r \subseteq Q \times \Sigma_{rel} \times \Phi(D) \times 2^{C_{st}} \times (I \cup \{\top\}) \times Q \) is the set of pop transitions,
- \( \Delta_i \subseteq Q \times \Sigma_{int} \times \Phi(D) \times 2^{C_{st}} \times Q \) is the set of internal transitions.

We now describe how a nested VPTA \( \mathcal{A} \) behaves over an infinite timed word \( w \). Assume that on reading the \( i \)-th position of \( w \), the current state of \( \mathcal{A} \) is \( q \), \( val^w_i \) is the event-clock valuation associated with \( w \) and \( i \), \( sval \) is the current valuation of the standard clocks in \( C_{st} \), and \( t = \tau_i - \tau_{i-1} \) is the time elapsed from the last transition (where \( \tau_{-1} = 0 \)). If \( \mathcal{A} \) reads a call \( c \in \Sigma_{call} \), it chooses a push transition of the form \((q, c, \theta, Res, q', \gamma) \in \Delta_c \) and pushes the symbol \( \gamma \neq \perp \) onto the stack. If \( \mathcal{A} \) reads a return \( r \in \Sigma_{rel} \), it chooses a pop transition of the form \((q, r, \theta, Res, \gamma, q') \in \Delta_r \), such that \( \gamma \) is the symbol on top of the stack, and pops \( \gamma \) from the stack (if \( \gamma = \perp \), then \( \gamma \) is read but not removed). Finally, on reading an internal action \( a \in \Sigma_{int} \), \( \mathcal{A} \) chooses an internal transition of the form \((q, a, \theta, Res, q') \in \Delta_i \), and, in this case, there is no operation on the stack. Moreover, in all the cases, the constraint \( \theta \) of the chosen transition must be fulfilled by the valuation \((sval + t) \cup (val^w_i)|_C \), the control changes from \( q \) to \( q' \), and all the standard clocks in \( Res \) are reset (i.e., the valuation of the standard clocks is updated to \((sval + t)[Res] \)).

Formally, a configuration of \( \mathcal{A} \) is a triple \((q, \beta, sval)\), where \( q \in Q, \beta \in I^* \cup \{\top\} \) is a stack content, and \( sval \) is a valuation over \( C_{st} \). A run \( \pi \) of \( \mathcal{A} \) over \( w = (\sigma, \tau) \) is an infinite sequence of configurations \( \pi = (q_0, \beta_0, sval_0), (q_1, \beta_1, sval_1), \ldots \) such that \( q_0 \in Q_0 \), \( \beta_0 = \top \), \( sval_0(z) = 0 \) for all \( z \in C_{st} \) (initialization requirement), and the following holds for all \( i \geq 0 \), where \( t_i = \tau_i - \tau_{i-1} (\tau_{-1} = 0) \):

- **Push:** If \( \sigma_i \in \Sigma_{call} \), then for some \((q_i, \sigma_i, \theta, Res, q_{i+1}, \gamma) \in \Delta_c, \beta_{i+1} = \gamma \cdot \beta_i, sval_{i+1} = (sval_i + t_i)[Res], \) and \((val^w_i)|_C \models \theta \).
- **Pop:** If \( \sigma_i \in \Sigma_{rel} \), then for some \((q_i, \sigma_i, \theta, Res, \gamma, q_{i+1}) \in \Delta_r, sval_{i+1} = (sval_i + t_i)[Res], (val^w_i)|_C \models \theta \), and either \( \gamma \neq \perp \) and \( \beta_i = \gamma \cdot \beta_{i+1} \), or \( \gamma = \beta_i = \beta_{i+1} = \top \).
- **Internal:** If \( \sigma_i \in \Sigma_{int} \), then for some \((q_i, \sigma_i, \theta, Res, q_{i+1}) \in \Delta_i, \beta_{i+1} = \beta_i, sval_{i+1} = (sval_i + t_i)[Res], \) and \((sval_i + t_i) \cup (val^w_i)|_C \models \theta \).
The run \( \pi \) is accepting if there are infinitely many positions \( i \geq 0 \) such that \( q_i \in F \). The timed language \( L_T(\mathcal{A}) \) of \( \mathcal{A} \) is the set of infinite timed words \( w \) over \( \Sigma \) such that there is an accepting run of \( \mathcal{A} \) on \( w \). The greatest constant of \( \mathcal{A} \), denoted \( K_\mathcal{A} \), is the greatest natural number used as bound in some clock constraint of \( \mathcal{A} \). For technical convenience, we also consider nested VPTA equipped with a generalized Büchi acceptance condition \( \mathcal{F} \) consisting of a family of sets of accepting states. In such a setting, a run \( \pi \) is accepting if for each Büchi component \( F \in \mathcal{F} \), the run \( \pi \) visits infinitely often states in \( F \).

A VPTA \([14]\) corresponds to a nested VPTA whose set \( C \) of event clocks is empty. An ECNA is a nested VPTA whose set \( C_{st} \) of standard clocks is empty. For ECNA, we can omit the reset component \( \text{Res} \) from the transition function and the valuation component \( sval \) from each configuration \( (q, \beta, sval) \). Note the the class of Event-Clock Visibly Pushdown Automata (ECVPA) \([17]\) corresponds to the subclass of ECNA where abstract and caller event-clocks are disallowed. We also consider three additional subclasses of ECNA: abstract predicting ECNA (AP,ECNA, for short) which do not use abstract recorder clocks and caller clocks, abstract recording ECNA (AR,ECNA, for short) which do not use abstract predictor clocks and caller clocks, and caller ECNA (C,ECNA, for short) which do not use abstract clocks. Note that these three subclasses of ECNA subsume ECVPA.

Example 1. Let us consider the AR,ECNA depicted below, where \( \Sigma_{\text{call}} = \{c\} \), \( \Sigma_{\text{ret}} = \{r\} \), and \( \Sigma_{\text{int}} = \{a,b,1\} \). The control part of the transition relation ensures that for each accepted word, the MAP visiting the \( b\)-position associated with the transition \( tr \) from \( q_4 \) to \( q_5 \) cannot visit the \( a\)-positions following the call positions. This implies that the abstract recorder constraint \( x^a_0 = 1 \) associated with \( tr \) is fulfilled only if all the occurrences of calls \( c \) and returns \( r \) are matched. Hence, constraint \( x^a_0 = 1 \) ensures that the accepted language, denoted by \( L_T^{rec} \),

consists of all the timed words of the form \( \sigma \cdot r^+ \cdot (r^\omega, \tau') \) such that \( \sigma \) is a well-matched word of the form \( a^+ \cdot c^+ \cdot a^+ \cdot r^+ \cdot b^+ \) and the time difference in \( (\sigma, \tau) \) between the first and last symbols is 1, i.e. \( \tau|\sigma|_1 - \tau_0 = 1 \). The example shows that ECNA allow to express a meaningful real-time property of recursive systems, namely the ability of bounding the time required to perform an internal activity consisting of an unbounded number of returning recursive procedure calls.

Similarly, it is easy to define an AP,ECNA accepting the timed language, denoted by \( L_T^{pred} \), consisting of all the timed words of the form \( (\sigma, \tau) \cdot (r^\omega, \tau) \) such that \( \sigma \) is a well-matched word of the form \( a^+ \cdot c^+ \cdot b^+ \cdot r^+ \cdot b \) and the time difference in \( (\sigma, \tau) \) between the two extreme symbols is 1.

Finally, as an example of language which can be defined by a C,ECNA, we consider the timed language \( L_T^{alter} \) consisting of the timed words of the form \( (c, t_0) \cdot (\sigma, \tau) \cdot (r^\omega, \tau') \) such that \( \sigma \) is a well-matched word of the form \( a^+ \cdot c^+ \cdot a^+ \cdot r^+ \cdot b^+ \) and the time difference in \( (c, t_0) \cdot (\sigma, \tau) \) between the first and last symbols is 1.
Closure properties of Büchi ECNA. As stated in the following theorem, the class of languages accepted by Büchi ECNA is closed under Boolean operations. The proof exploits a technique similar to that used in [17] to prove the analogous closure properties for ECVPA (for details, see Appendix A).

Theorem 1. The class of ω-timed languages accepted by Büchi ECNA is closed under union, intersection, and complementation. In particular, given two Büchi ECNA $A = (\Sigma, Q, Q_0, C, \Gamma \cup \{\top\}, \Delta, F)$ and $A' = (\Sigma, Q', Q'_0, C', \Gamma' \cup \{\top\}, \Delta', F')$ over $\Sigma_T$, one can construct

- a Büchi ECNA accepting $L_T(A) \cup L_T(A')$ with $|Q| + |Q'|$ states, $|\Gamma| + |\Gamma'| + 1$ stacks symbols, and greatest constant $\max(K_A, K_{A'})$;
- a Büchi ECNA accepting $L_T(A) \cap L_T(A')$ with $2|Q||Q'|$ states, $|\Gamma||\Gamma'|$ stacks symbols, and greatest constant $\max(K_A, K_{A'})$;
- a Büchi ECNA accepting the complement of $L_T(A)$ with $2O(n^2)$ states, $O(2O(n^2))$ stack symbols, and greatest constant $K_A$, where $n = |Q|$ and Const is the set of constants used in the clock constraints of $A$.

Expressiveness results. We now summarize the expressiveness results for ECNA. First of all, the timed languages $L_T^{rec}$, $L_T^{pred}$, and $L_T^{caller}$ considered in Example 1 and definable by AR,AP,ECNA, and C,ECNA, respectively, can be used to prove that the three subclasses $AR, AP, ECNA$, and $C,ECNA$ of ECNA are mutually incomparable. Hence, these subclasses strictly include the class of ECVPA and are strictly included in ECNA. The incomparability result directly follows from Proposition 1 below, whose proof is in Appendix B.

As for ECNA, we have that they are less expressive than Büchi VPTA. In fact, by Theorem 3 in Section 4, Büchi ECNA can be converted into equivalent Büchi VPTA. The inclusion is strict since, while Büchi ECNA are closed under complementation (Theorem 1), Büchi VPTA are not [13].

In [9], an equally-expressive extension of ECVPA over finite timed words, by means of a timed stack, is investigated. The Büchi version of such an extension can be trivially encoded in Büchi AR,ECNA. Moreover, the proof of Proposition 1 can also be used for showing that Büchi ECVPA with timed stack are less expressive than Büchi AR,ECNA, Büchi AP,ECNA, and Büchi C,ECNA.

The general picture of the expressiveness results is summarized by Theorem 2.

Proposition 1. The language $L_T^{rec}$ is not definable by Büchi ECNA which do not use abstract recorder clocks, $L_T^{pred}$ is not definable by Büchi ECNA which do not use abstract predictor clocks, and $L_T^{caller}$ is not definable by Büchi ECNA which do not use caller clocks. Moreover, the language $L_T^{rec} \cup L_T^{pred} \cup L_T^{caller}$ is not definable by Büchi AR,ECNA, Büchi AP,ECNA and Büchi C,ECNA.

Theorem 2. The classes $AR,AP,ECNA$, and $C,ECNA$ are mutually incomparable, and $AP,ECNA \cup AR,ECNA \cup C,ECNA \subset ECNA$. Moreover,

1. $ECVA \subset AR,ECNA$
2. $ECVA \subset AP,ECNA$
3. $ECVA \subset C,ECNA$
4. $ECVA \subset VPTA$

Note that the expressiveness results above also hold for the automata version over finite timed words.
4 Decision procedures for Büchi ECNA

In this section, we investigate the following decision problems:

- Emptiness, universality, and language inclusion for Büchi ECNA.
- Visibly model-checking problem against Büchi ECNA: given a visibly push-down timed system $S$ over $\Sigma$ (that is a Büchi VPTA where all the states are accepting) and a Büchi ECNA $A$ over $\Sigma$, does $L_T(S) \subseteq L_T(A)$ hold?

We establish that the above problems are decidable and EXPTIME-complete. The key intermediate result is an exponential-time translation of Büchi ECNA into language-equivalent generalized Büchi VPTA. More precisely, we show that event clocks in nested VPTA can be removed with a single exponential blow-up.

**Theorem 3 (Removal of event clocks from nested VPTA).** Given a generalized Büchi nested VPTA $A$, one can construct in singly exponential time a generalized Büchi VPTA $A'$ (which do not use event clocks) such that $L_T(A') = L_T(A)$ and $K_A = K_{A'}$. Moreover, $A'$ has $n \cdot 2^{O(p \cdot |I|)}$ states and $m + O(p)$ clocks, where $n$ is the number of $A$-states, $m$ is the number of standard $A$-clocks, and $p$ is the number of event-clock atomic constraints used by $A$.

In the following we sketch a proof of Theorem 3. Basically, the result follows from a sequence of transformation steps all preserving language equivalence. At each step, an event clock is replaced by a set of fresh standard clocks. To remove global event clocks we use the technique from [4]. Here, we focus on the removal of an abstract predictor clock $y_b^a$ with $b \in \Sigma$, referring to Appendix D and E for the treatment of abstract recorder clocks and caller clocks.

Fix a generalized Büchi nested VPTA $A = (\Sigma, Q, Q_0, C \cup C_{st}, \Gamma \cup \{\top\}, \Delta, \mathcal{F})$ such that $y_b^a \in C$. By exploiting nondeterminism, we can assume that for each transition $tr$ of $A$, there is exactly one atomic constraint $y_b^a \in I$ involving $y_b^a$ used as conjunct in the clock constraint of $tr$. If $I \neq \{\bot\}$, then $y_b^a \in I$ is equivalent to a constraint of the form $y_b^a > \ell \land y_b^a < u$, where $\ell \in \{>, \geq\}$, $u \in \{<, \leq\}$, $\ell \in \mathbb{N}$, and $u \in \mathbb{N} \cup \{\infty\}$. We call $y_b^a > \ell$ (resp., $y_b^a < u$) a lower-bound (resp., upper-bound) constraint. Note that if $u = \infty$, the constraint $y_b^a < u$ is always fulfilled, but we include it to have a uniform notation. We construct a generalized Büchi nested VPTA $A_{st}$ equivalent to $A$ whose set of event clocks is $C \setminus \{y_b^a\}$, and whose set of standard clocks is $C_{st} \cup C_{new}$, where $C_{new}$ consists of the fresh standard clocks $z_{\geq\ell}$ (resp., $z_{<u}$), for each lower-bound constraint $y_b^a > \ell$ (resp., upper-bound constraint $y_b^a < u$) of $A$ involving $y_b^a$.

We now report the basic ideas of the translation. Consider a lower-bound constraint $y_b^a > \ell$. Assume that a prediction $y_b^a > \ell$ is done by $A$ at position $i$ of the input word for the first time. Then, the simulating automaton $A_{st}$ exploits the standard clock $z_{\geq\ell}$ to check that the prediction holds by resetting it at position $i$. Moreover, if $i$ is not a call (resp., $i$ is a call), $A_{st}$ carries the obligation $\geq\ell$ in its control state (resp., pushes the obligation $\geq\ell$ onto the stack) in order to check that the constraint $z_{\geq\ell} > \ell$ holds when the next $b$ occurs at a position $j_{\text{check}}$ along the MAP $\nu$ visiting position $i$. We observe that:
that fresh upper-bound obligations (bound obligations are propagated from the caller MAP \( \nu \)) live obligation (\( i \) stack in order to be recovered at the matching return \( i \)).

- If a call position \( i_c \geq i \) occurs in \( \nu \) before \( j_{\text{check}} \), the next position of \( i_c \) in \( \nu \) is the matching return \( i_r \) of \( i_c \), and any MAP visiting a position \( h \in [i_c + 1, i_r - 1] \) is finite and ends at a position \( k < i_r \). Thus, the clock \( z_{\succ \ell} \) can be safely reset to check the prediction \( y_b^i \succ \ell \) raised in positions in \([i_c + 1, i_r - 1]\) since this check ensures that \( z_{\succ \ell} \succ \ell \) holds at position \( j_{\text{check}} \).

Thus, previous obligations on a constraint \( y_b^i \succ \ell \) are always rewritten by more recent ones. At each position \( i \), \( A_{y_b^i} \) records in its control state the lower-bound obligations for the current MAP \( \nu \) (i.e., the MAP visiting the current position \( i \)). Whenever a call \( i_c \) occurs, the lower-bound obligations are pushed on the stack in order to be recovered at the matching return \( i_r \). If \( i_c + 1 \) is not a return (i.e., \( i_c \neq i_r + 1 \)), then \( A_{y_b^i} \) moves to a control state having an empty set of lower-bound obligations (position \( i_c + 1 \) starts the MAP visiting \( i_c + 1 \)).

The treatment of an upper-bound constraint \( y_b^i \prec u \) is symmetric. Whenever a prediction \( y_b^i \prec u \) is done by \( A \) at a position \( i \), and the simulating automaton \( A_{y_b^i} \) has no obligation on the constraint \( y_b^i \prec u \), \( A_{y_b^i} \) resets the standard clock \( z_{\prec u} \). If \( i \) is not a call (resp., \( i \) is a call) the fresh obligation \((\text{first}, \prec u)\) is recorded in the control state (resp., \((\text{first}, \prec u)\) is pushed onto the stack). When, along the MAP \( \nu \) visiting position \( i \), the next \( b \) occurs at a position \( j_{\text{check}} \), the constraint \( z_{\prec u} \prec u \) is checked, and the obligation \((\text{first}, \prec u)\) is removed or confirmed (in the latter case, resetting the clock \( z_{\prec u} \)), depending on whether the prediction \( y_b^i \prec u \) is asserted at position \( j_{\text{check}} \) or not. We observe that:

- If a new prediction \( y_b^i \prec u \) occurs in a position \( j > i \) of \( \nu \) strictly preceding \( j_{\text{check}} \), \( A_{y_b^i} \) simply ignores it (the clock \( z_{\prec u} \) is not reset at position \( j \)) since checking the prediction \( y_b^i \prec u \) at the previous position \( i \) guarantees the fulfillment of the prediction \( y_b^i \prec u \) at the position \( j > i \) along \( \nu \).

- If a call position \( i_c \geq i \) occurs in \( \nu \) before \( j_{\text{check}} \), then all the predictions \( y_b^i \prec u \) occurring in a MAP visiting a position \( h \in [i_c + 1, i_r - 1] \), with \( i_r \leq j_{\text{check}} \) being the matching-return of \( i_c \), can be safely ignored (i.e., \( z_{\prec u} \) is not reset there) since they are subsumed by the prediction at position \( i \).

Thus, for new obligations on an upper-bound constraint \( y_b^i \prec u \), the clock \( z_{\prec u} \) is not reset. Whenever a call \( i_c \) occurs, the updated set \( O \) of upper-bound and lower-bound obligations is pushed onto the stack to be recovered at the matching return \( i_r \) of \( i_c \). Moreover, if \( i_c + 1 \) is not a return (i.e., \( i_r \neq i_c + 1 \)), then \( A_{y_b^i} \) moves to a control state where the set of lower-bound obligations is empty and the set of upper-bound obligations is obtained from \( O \) by replacing each upper-bound obligation \((f, \prec u)\), for \( f \in \{\text{live}, \text{first}\} \), with the live obligation \((\text{live}, \prec u)\). The latter asserted at the initial position \( i_c + 1 \) of the MAP \( \nu \) visiting \( i_c + 1 \) (note that \( \nu \) ends at \( i_r - 1 \)) is used by \( A_{y_b^i} \) to remember that the clock \( z_{\prec u} \) cannot be reset along \( \nu \). Intuitively, live upper-bound obligations are propagated from the caller MAP to the called MAP. Note that fresh upper-bound obligations \((\text{first}, \prec u)\) always refer to predictions done
along the current MAP and, differently from the live upper-bound obligations, they can be removed when the next $b$ occurs along the current MAP.

Extra technicalities are needed. At each position $i$, $A_{\nu \delta}$ guesses whether $i$ is the last position of the current MAP (i.e., the MAP visiting $i$). For this, it keeps track in its control state of the guessed type (call, return, or internal symbol) of the next input symbol. In particular, when $i$ is a call, $A_{\nu \delta}$ guesses whether it has a matching return. If not, $A_{\nu \delta}$ pushes onto the stack a special symbol, say bad, and the guess is correct iff the symbol is never popped from the stack. Conversely, $A_{\nu \delta}$ exploits a special proposition $p_\infty$ whose Boolean value is carried in the control state: $p_\infty$ does not hold at a position $j$ of the input iff the MAP visiting $j$ has a caller whose matching return exists. Note that $p_\infty$ holds at infinitely many positions. The transition function of $A_{\nu \delta}$ ensures that the Boolean value of $p_\infty$ is propagated consistently with the guesses. Doing so, the guesses about the matched calls are correct iff $p_\infty$ is asserted infinitely often along a run. A Büchi component of $A_{\nu \delta}$ ensures this last requirement. Finally, we have to ensure that the lower-bound obligations and fresh upper-bound obligations at the current position are eventually checked, i.e., the current MAP eventually visits a $b$-position. For finite MAP, this can be ensured by the transition function of $A_{\nu \delta}$. For infinite MAP, we note that at most one infinite MAP $\nu$ exists along a word, and $\nu$ visits only positions where $p_\infty$ holds. Moreover, each position $i$ greater than the initial position $i_0$ of $\nu$ is either a $\nu$-position, or a position where $p_\infty$ does not hold. Thus, a Büchi component of $A_{\nu \delta}$ using proposition $p_\infty$ ensures the $b$-liveness requirements along the unique infinite MAP (if any). Full details of the construction of $A_{\nu \delta}$ are in Appendix C.

By exploiting Theorems 1 and 3, we establish the main result of the paper.

**Theorem 4.** Emptiness, universality, and language inclusion for Büchi ECNA, and visibly model-checking against Büchi ECNA are Exptime-complete.

**Proof.** For the upper bounds, first observe ([10]) that the emptiness problem of generalized Büchi VPTA is Exptime-complete and solvable in time $O(n^4 \cdot 2^{O(m \log Km)})$, where $n$ is the number of states, $m$ is the number of clocks, and $K$ is the largest constant used in the clock constraints of the automaton. Now, given two Büchi ECNA $A_1$ and $A_2$ over $\Sigma$, checking whether $L_T(A_1) \subseteq L_T(A_2)$ reduces to check emptiness of the language $L_T(A_1) \cap L_T(A_2)$. Similarly, given a Büchi VPTA $S$ where all the states are accepting and a Büchi ECNA $A$ over the same pushdown alphabet $\Sigma$, model-checking $S$ against $A$ reduces to check emptiness of the language $L_T(S) \cap L_T[A]$. Since Büchi VPTA are polynomial-time closed under intersection and universality can be reduced in linear-time to language inclusion, by the closure properties of Büchi ECNA (Theorem 1 and Theorem 3), membership in Exptime for the considered problems directly follow.

For the matching lower-bounds, the proof of Exptime-hardness for emptiness of Büchi VPTA can be easily adapted to the class of Büchi ECNA. For the other problems, the result directly follows from Exptime-hardness of the corresponding problems for Büchi VPA ([5,6]) which are subsumed by Büchi ECNA. \qed
Conclusions. In this paper we have introduced and studied ECNA, a robust subclass of VPTA allowing to express meaningful non-regular timed properties of recursive systems. The closure under Boolean operations, and the decidability of languages inclusion and visibly model-checking makes ECNA amenable to specification and verification purposes. As future work, we plan to investigate suitable extensions of the Event Clock Temporal Logic introduced for ECA so that a logical counterpart for ECNA can be similarly recovered.

Appendix

A  Proof of Theorem 1

In this section, we provide a proof of the following result.

**Theorem 1 (Closure properties).** The class of $\omega$-timed languages accepted by Büchi ECNA is closed under union, intersection, and complementation. In particular, given two Büchi ECNA $A = (\Sigma, Q, Q_0, C, \Gamma \cup \{\top\}, \Delta, F)$ and $A' = (\Sigma, Q', Q'_0, C', \Gamma' \cup \{\top\}, \Delta', F')$ over $\Sigma$, one can construct

- a Büchi ECNA accepting $L_T(A) \cup L_T(A')$ with $|Q| + |Q'|$ states, $|\Gamma| + |\Gamma'| + 1$ stacks symbols, and greatest constant $\max(K_A, K_{A'})$;
- a Büchi ECNA accepting $L_T(A) \cap L_T(A')$ with $2|Q||Q'|$ states, $|\Gamma||\Gamma'|$ stacks symbols, and greatest constant $\max(K_A, K_{A'})$;
- a Büchi ECNA accepting the complement of $L_T(A)$ with $2^{O(n^2)}$ states, $O(2^{O(n^2)})$, $|\Sigma_{call}| + |\text{Const}|^{O(1)}$ stack symbols, and greatest constant $K_A$, where $n = |Q|$ and $\text{Const}$ is the set of constants used in the clock constraints of $A$.

Let $A = (\Sigma, Q, Q_0, C, \Gamma \cup \{\top\}, \Delta, F)$ and $A' = (\Sigma, Q', Q'_0, C', \Gamma' \cup \{\top\}, \Delta', F')$ be two Büchi ECNA over $\Sigma$. Closure under union and intersection easily follows from the language closure properties of Büchi ECA and Büchi visibly pushdown automata (VPA). In particular, the Büchi ECNA accepting $L_T(A) \cup L_T(A')$ is obtained by taking the union of the states, stack symbols, and transitions of $A$ and $A'$ (assuming they are disjoint) and taking the new set of initial states (resp., final states) to be the union of the initial states (resp., final states) of $A$ and $A'$. The Büchi ECNA accepting $L_T(A) \cap L_T(A')$ has a set of states $Q \times Q' \times \{0, 1\}$, set of initial states $Q_0 \times Q'_0 \times \{0\}$, stack alphabet $(\Gamma \times \Gamma') \cup \{\top\}$, and set of accepting states $Q \times F' \times \{1\}$. When reading a call, if $A$ pushes $\gamma$ and $A'$ pushes $\gamma'$, then the product automaton pushes $(\gamma, \gamma')$. We exploit the fact that $A$ and $A'$, being ECNA over the same pushdown alphabet, synchronize on the push and pop operations on the stack. The additional flag in the set of states is used to ensure that the final states of both automata are visited infinitely often.

It remains to prove the closure under language complementation. For this, we adopt the approach exploited in [17] for the subclass of Büchi ECVPA. In particular, we define an homomorphism from Büchi ECNA to Büchi VPA and vice versa. Note that a Büchi VPA is defined as a Büchi ECNA but we omit the set of event clocks, and the set of clock constraints from the transition function. The notion of (accepting) run of a Büchi VPA over an infinite word on $\Sigma$ is similar to the notion of (accepting) run of an ECNA over an infinite timed word on $\Sigma$, but we omit the requirements about the clock constraints.

Fix a Büchi ECNA $A = (\Sigma, Q, Q_0, C, \Gamma \cup \{\top\}, \Delta, F)$ and let $\text{Const} = \{c_0, \ldots, c_k\}$ be the set of constants used in the clock constraints of $A$ ordered for increasing values, i.e. such that $0 \leq c_0 < c_1 < \ldots < c_k$. We consider the following set $\text{Intv}$ of intervals over $\mathbb{R}_+ \cup \{\bot\}$:

$$\text{Intv} := \{[\bot, \bot], [0, 0], (0, c_0)\} \cup \bigcup_{i=0}^{i=k-1} \{(c_i, c_i), (c_i, c_{i+1})\} \cup \{(c_k, c_k), (c_k, \infty)\}$$
A region $g$ of $\mathcal{A}$ is a mapping $g : C \mapsto \text{Intv}$ assigning to each event clock in $C \subseteq C_{\Sigma}$ an interval in $\text{Intv}$. The mapping $g$ induces the clock constraint $\bigwedge_{z \in C} z \in g(z)$. We denote by $[g]$ the set of valuations over $C$ satisfying the clock constraint associated with $g$, and by $\text{Reg}$ the set of regions of $\mathcal{A}$. For a clock constraint $\theta$ over $C$, let $[\theta]$ be the set of valuations over $C$ satisfying $\theta$.

**Remark 1.** By construction, the following holds.

- The set $\text{Reg}$ of regions represents a partition of the set of clock valuations over $C$, i.e., (i) for all valuations $\text{val}$ over $C$, there is a region $g \in \text{Reg}$ such that $\text{val} \in [g]$, and (ii) for all regions $g, g' \in \text{Reg}$, $g \neq g' \Rightarrow [g] \cap [g'] = \emptyset$.

- For each clock constraint $\theta$ of $\mathcal{A}$ and region $g \in \text{Reg}$, either $[g] \subseteq [\theta]$ or $[g] \cap [\theta] = \emptyset$.

We associate with $\Sigma = \Sigma_{\text{call}} \cup \Sigma_{\text{ret}} \cup \Sigma_{\text{int}}$ and the set of regions $\text{Reg}$ a pushdown alphabet $\Lambda = \Sigma \times \text{Reg}$, called interval pushdown alphabet, whose set of calls is $\Sigma_{\text{call}} \times \text{Reg}$, whose set of returns is $\Sigma_{\text{ret}} \times \text{Reg}$, and whose set of internal actions is $\Sigma_{\text{int}} \times \text{Reg}$. Elements of $\Lambda$ are pairs of the form $(a, g)$, where $a \in \Sigma$ and $g$ is a region of $\mathcal{A}$ which is meant to represent the associated constraint $\bigwedge_{z \in C} z \in g(z)$. An infinite word $\lambda = (a_0, g_0), (a_1, g_1), \ldots$ over $\Lambda$ induces in a natural way a set of infinite timed words over $\Lambda$, denoted $\text{tw}(\lambda)$, defined as follows: $w = (\sigma, \tau) \in \text{tw}(\lambda)$ iff $\sigma = a_0a_1\ldots$ and for all $i \geq 0$, $\text{val}_i^w \in [g_i]$. We extend the mapping $\text{tw}$ to $\omega$-languages $\mathcal{L}$ over $\Lambda$ in the obvious way: $\text{tw}(\mathcal{L}) := \bigcup_{\lambda \in \mathcal{L}} \text{tw}(\lambda)$. By means of the mapping $\text{tw}$, infinite words over $\Lambda$ define a partition of the set of infinite timed words over $\Sigma$.

**Lemma 1.** The following holds.

1. For each infinite timed word $w = (\sigma, \tau)$ over $\Sigma$, there is an infinite word $\lambda$ over $\Lambda$ of the form $(\sigma_0, g_0)(\sigma_1, g_1)$ such that $w \in \text{tw}(\lambda)$.

2. For all infinite words $\lambda$ and $\lambda'$ over $\Lambda$, $\lambda \neq \lambda' \Rightarrow \text{tw}(\lambda) \cap \text{tw}(\lambda') = \emptyset$.

**Proof.** For Property 1, let $w = (\sigma, \tau)$ be an infinite timed word over $\Lambda$. By Remark 1 for all $i \geq 0$, there is a region $g_i \in \text{Reg}$ such that $\text{val}_i^w \in [g_i]$. Let $\lambda = (\sigma_0, g_0)(\sigma_1, g_1)\ldots$. We have that $w \in \text{tw}(\lambda)$, and the result follows.

For Property 2, let $\lambda$ and $\lambda'$ be two distinct infinite words over $\lambda$. Let us assume that $\text{tw}(\lambda) \cap \text{tw}(\lambda') \neq \emptyset$ and derive a contradiction. Hence, by construction, $\lambda = (a_0, g_0)(a_1, g_1)\ldots$, $\lambda' = (a_0', g_0')(a_1, g_1')\ldots$, and there is an infinite timed word $w$ over $\Lambda$ of the form $(a_0, \tau_0)(a_1, \tau_1)$ such that $\text{val}_i^w \in [g_i] \cap [g_i']$ for all $i \geq 0$. Since $\lambda \neq \lambda'$, there exists $n \geq 0$ such that $g_n \neq g_n'$. By Remark 1 $[g_n] \cap [g_n'] = \emptyset$ which is a contradiction since $\text{val}_n^w \in [g_n] \cap [g_n']$, and the result follows.

The following two propositions, establish an untimed homomorphism from Büchi ECNA to Büchi VPA, and a timed homomorphism from Büchi VPA to Büchi ECNA, respectively.

**Proposition 2 (Untimed homomorphism).** Let $\mathcal{A} = (\Sigma, Q, Q_0, C, \Gamma \cup \{\top\}, \Delta, F)$ be a Büchi ECNA, and $\Lambda$ be the interval pushdown alphabet induced by $\mathcal{A}$. Then, one can construct a Büchi VPA Untimed$(\mathcal{A})$ over $\Lambda$ of the form $(\Lambda, Q, Q_0, \Gamma \cup \{\top\}, \Delta', F)$ such that $\text{tw}(\mathcal{L}(\text{Untimed}(\mathcal{A}))) = \mathcal{L}_\tau(\mathcal{A})$. 
Proof. The transition function $\Delta'$ of $\text{Untimed}(A)$ is defined as follows:

- Push: If $(q, c, \theta, q', \gamma)$ is a push transition in $\Delta$, then for each region $g$ of $A$ such that $[g] \subseteq [\theta]$, $(q, (c, g), q', \gamma) \in \Delta'$.
- Pop: If $(q, r, \theta, \gamma, q')$ is a pop transition in $\Delta$, then for each region $g$ of $A$ such that $[g] \subseteq [\theta]$, $(q, (r, g), \gamma, q') \in \Delta'$.
- Internal: If $(q, a, \theta, q')$ is an internal transition in $\Delta$, then for each region $g$ of $A$ such that $[g] \subseteq [\theta]$, $(q, (a, g), q') \in \Delta'$.

By Remark 1 and Lemma 1(1), we easily derive the correctness of the construction.

Proposition 3 (Timed homomorphism). Let $A = (A, Q, Q_0, \Gamma \cup \{\top\}, \Delta, F)$ be a Büchi VPA over an interval pushdown alphabet associated with $\Sigma$ and a set $C \subseteq C_\Sigma$ of event clocks. Then, one can construct a Büchi ECNA $\text{Timed}(A)$ over $\Sigma$ of the form $(\Sigma, Q, Q_0, C, \Gamma \cup \{\top\}, \Delta', F)$ such that $L_T(\text{Timed}(A)) = \text{tw}(L(A))$.

Proof. The transition function $\Delta'$ of $\text{Timed}(A)$ is defined as follows:

- Push: If $(q, (c, g), q', \gamma)$ is a push transition in $\Delta$, then $(q, (c, g), q', \gamma) \in \Delta'$ where $\theta := \bigwedge_{z \in C} z \in g(z)$.
- Pop: If $(q, (r, g), \gamma, q')$ is a pop transition in $\Delta$, then $(q, (r, g), \gamma, q') \in \Delta'$ where $\theta := \bigwedge_{z \in C} z \in g(z)$.
- Internal: If $(q, (r, g), q')$ is an internal transition in $\Delta$, then $(q, (r, g), q') \in \Delta'$ where $\theta := \bigwedge_{z \in C} z \in g(z)$.

By Remark 1 and Lemma 1(1), we easily derive the correctness of the construction.

By Lemma 1, Propositions 2 and 3, and the known closure properties of Büchi Visibly Pushdown Automata (VPA), we have the following result.

Theorem 5 (Closure under complementation). Given a Büchi ECNA $A$ over $\Sigma$ with $n$ states and set of constants Const, one can construct in singly exponential time a Büchi ECNA $A$ over $\Sigma$ accepting the complement of $L_T(A)$ having $2^{O(n^2)}$ states and $O(2^{O(n^2)} \cdot |\Sigma_{call}| \cdot \text{Const}^{O(1)}})}$ stack symbols.

Proof. Let $A$ be a Büchi ECNA over $\Sigma$ with $n$ states and set of integer constants Const, $A$ be the interval pushdown alphabet induced by $A$, and $A_c$ be the set of calls in $A$. By Proposition 2, we can construct a Büchi VPA $\text{Untimed}(A)$ over $A$ with $n$ states such that $\text{tw}(L(\text{Untimed}(A))) = L_T(A)$. By 56, starting from the Büchi VPA $\text{Untimed}(A)$, one can construct in singly exponential time a Büchi VPA $\text{Timed}(A)$ over $A$ accepting $A_{\omega} \setminus L(\text{Untimed}(A))$ with $2^{O(n^2)}$ states and $O(2^{O(n^2)} \cdot |A_c|)$ stack symbols. Applying Proposition 3 to the Büchi VPA $\text{Untimed}(A)$, one can construct in linear time a Büchi ECNA $\A$ over $\Sigma$ with $2^{O(n^2)}$ states and $O(2^{O(n^2)} \cdot |A_c|)$ stack symbols such that $L_T(\A) = \text{tw}(A_{\omega} \setminus L(\text{Timed}(A)))$. Since $L_T(A) = \text{tw}(L(\text{Untimed}(A)))$, by Lemma 1, $\A$ accepts all and only the infinite timed words over $\Sigma$ which are not in $L_T(A)$. Thus, since $|A_c| = O(|\Sigma_{call}| \cdot \text{Const}^{O(1)}})$, the result follows.
B Inexpressiveness results: proof of Proposition 1

Let $\Sigma = \Sigma_{\text{call}} \cup \Sigma_{\text{rel}} \cup \Sigma_{\text{int}}$ be the pushdown alphabet with $\Sigma_{\text{call}} = \{c\}$, $\Sigma_{\text{rel}} = \{r\}$, and $\Sigma_{\text{int}} = \{a, b, 1\}$. Let us consider the timed languages $L_{\text{rec}}^T$, $L_{\text{pred}}^T$, and $L_{\text{call}}^T$ over $\Sigma$ in Example 1. We show the following result.

**Proposition 1.** The language $L_{\text{rec}}^T$ is not definable by Büchi ECNA which do not use abstract recorder clocks, $L_{\text{pred}}^T$ is not definable by Büchi ECNA which do not use abstract predictor clocks, and $L_{\text{call}}^T$ is not definable by Büchi ECNA which do not use call clocks. Moreover, the language $L_{\text{rec}}^T \cup L_{\text{pred}}^T \cup L_{\text{call}}^T$ is not definable by Büchi AR(ECNA), Büchi AP(ECNA) and Büchi C(ECNA).

**Proof.** First, let us consider the timed language $L_{\text{rec}}^T$. Recalling Example 1, $L_{\text{rec}}^T$ consists of all the timed words of the form $(\sigma, \tau) \cdot (i^r, i^\omega)$ such that $\sigma$ is a well-matched word of the form $a \cdot c^+ \cdot a^+ \cdot r^+ \cdot b^+$ and the time difference in $(\sigma, \tau)$ between the first and last symbols is 1. Let $v_1$ and $v_2$ be the finite timed words over $\Sigma$ of length 6 defined as follows.

- $v_1 = (a, 0) \cdot (c, 0.1) \cdot (a, 0.1) \cdot (r, 0.1) \cdot (b, 0.1) \cdot (b, 0.9)$.
- $v_2 = (a, 0) \cdot (c, 0.1) \cdot (a, 0.1) \cdot (r, 0.1) \cdot (b, 0.1) \cdot (b, 1)$.

For each $H \geq 1$, let $w_1^H = v_1 \cdot (i, H + 2) \cdot (i, H + 3) \ldots$ and $w_2^H = v_2 \cdot (i, H + 2) \cdot (i, H + 3) \ldots$. Let us denote by $\text{val}^1_{\Sigma} H$ and $\text{val}^2_{\Sigma} H$ the event-clock valuations over $C_{\Sigma}$ associated with $w_1^H$ and $w_2^H$, respectively. By construction, the following easily follows for all positions $i \geq 0$ and event-clocks $z \in C_{\Sigma}$ such that $z$ is not an abstract recorder clock:

- either (i) $\text{val}^1_{\Sigma} H(z) = \text{val}^2_{\Sigma} H(z)$, or (ii) $0 < \text{val}^1_{\Sigma} H(z) < 1$ and $0 < \text{val}^2_{\Sigma} H(z) < 1$, or (iii) $\text{val}^1_{\Sigma} H(z) > H$ and $\text{val}^2_{\Sigma} H(z) > H$.

Hence, clock constraints which do not use abstract recorder clocks and whose maximum constant is at most $H$ cannot distinguish the valuations $\text{val}^1_{\Sigma} H$ and $\text{val}^2_{\Sigma} H$. It follows that for each ECNA $A$ over $\Sigma$ which does not use abstract recorder clocks and has maximum constant $H$, $w_1^H \in L_{\text{rec}}^T(A)$ iff $w_2^H \in L_{\text{rec}}^T(A)$. On the other hand, by definition of the language $L_{\text{rec}}^T$, for each $H \geq 1$, $w_1^H \in L_{\text{rec}}^T$ and $w_2^H \notin L_{\text{rec}}^T$. Hence, $L_{\text{rec}}^T$ is not definable by Büchi ECNA which do not use abstract recorder clocks.

Now, let us consider the timed language $L_{\text{pred}}^T$. Recall that $L_{\text{pred}}^T$ consists of all the timed words of the form $(\sigma, \tau) \cdot (i^r, i^\omega)$ such that $\sigma$ is a well-matched word of the form $a^+ \cdot c^+ \cdot b^+ \cdot r^+ \cdot b$ and the time difference in $(\sigma, \tau)$ between the two extreme symbols is 1. Let $u_1$ and $u_2$ be the finite timed words over $\Sigma$ of length 6 defined as follows.

- $u_1 = (a, 0) \cdot (a, 0.1) \cdot (c, 0.1) \cdot (b, 0.1) \cdot (r, 0.1) \cdot (b, 0.9)$.
- $u_2 = (a, 0) \cdot (a, 0.1) \cdot (c, 0.1) \cdot (b, 0.1) \cdot (r, 0.1) \cdot (b, 1)$.

For each $H \geq 1$, let $r_1^H = u_1 \cdot (i, H + 2) \cdot (i, H + 3) \ldots$ and $r_2^H = u_2 \cdot (i, H + 2) \cdot (i, H + 3) \ldots$. By reasoning as for the the case of the language $L_{\text{rec}}^T$, it easily follows that for each ECNA $A$ over $\Sigma$ which does not use abstract predictor
clocks and has as maximum constant $H$, $r_1^H \in \mathcal{L}_T(A)$ iff $r_2^H \in \mathcal{L}_T(A)$. On the other hand, by definition of the language $\mathcal{L}_T^{\text{pred}}$, for each $H \geq 1$, $r_2^H \in \mathcal{L}_T^{\text{pred}}$ and $r_1^H \notin \mathcal{L}_T^{\text{pred}}$. Hence, $\mathcal{L}_T^{\text{pred}}$ is not definable by Büchi ECNA which do not use abstract predictor clocks.

The proof for the timed language $\mathcal{L}_T^{\text{caller}}$ is similar. Finally, we observe that by the above considerations, it follows that $\mathcal{L}_T^{\text{rec}} \cup \mathcal{L}_T^{\text{pred}} \cup \mathcal{L}_T^{\text{caller}}$ is not definable neither by an abstract-predicting Büchi ECNA nor by an abstract-recording Büchi ECNA nor by a caller Büchi ECNA. \hfill \Box

## C Removal of abstract predictor clocks in nested VPTA

In this section, we provide the details of the construction of the generalized Büchi nested VPTA $A_{y^*}$ described in Section 4 starting from a generalized Büchi nested VPTA $A = (\Sigma, Q, Q_0, C \cup C_{st}, \Gamma \cup \{1\}, \Delta, \mathcal{F})$ such that the abstract predictor clock $x^*_a$ is in $C$. For this, we need additional notation.

An obligation set $O$ (for the fixed abstract predictor clock $y^*_a$ and the fixed generalized Büchi nested VPTA $A$) is a set consisting of lower-bound obligations $\succ \ell$ and upper-bound obligations $(f, \prec u)$, where $f \in \{\text{live, first}\}$, such that $y^*_b \succ \ell$ and $y^*_b \prec u$ are associated to interval constraints of $A$, and $(f, \prec u), (f', \prec u) \in O$ implies $f = f'$. For an obligation set $O$, $\text{live}(O)$ is the obligation set consisting of the live upper-bound obligations of $O$.

Let us consider the CaRet formula $\Box F^a b : F^a b$ holds at position $i \geq 0$ if the MAP visiting $i$ also visits a position $j \geq i$ where $b$ holds. A check set $H$ is a subset of $\{\text{call, ret, int, b, } F^a b, p_{\infty}\}$ such that $H \cap \{\text{call, ret, int}\}$ is a singleton. Intuitively, a check set is exploited by $A_{y^*_a}$ for keeping track of: (i) the guessed type (call, return, or internal symbol) of the next input symbol, (ii) whether the next input symbol is $b$, (iii) whether $p_{\infty}$ holds at the current position, and (iv) whether $F^a b$ holds at the current position.

Let $C_{\text{new}}$ be the set of standard clocks consisting of the fresh standard clocks $z_{\succ \ell}$ (resp., $z_{\prec u}$) for each lower-bound constraint $y^*_b \succ \ell$ (resp., upper-bound constraint $y^*_b \prec u$) of $A$ involving $y^*_a$. For an input symbol $a \in \Sigma$ and an obligation set $O$, we denote by $\text{con}(O, a)$ the constraint over the new set $C_{\text{new}}$ of standard clocks defined as: $\text{con}(O, a) = \text{true}$ if either $O = \emptyset$ or $a \neq b$; otherwise, $\text{con}(O, a)$ is obtained from $O$ by adding for each obligation $\succ \ell$ (resp., $(f, \prec u)$) in $O$, the conjunct $z_{\succ \ell} (\text{resp., } z_{\prec u} \prec u)$. The nested VPTA $A_{y^*_a}$ is given by

$$A_{y^*_a} = (\Sigma, Q', Q_0', C \setminus \{y^*_b\} \cup C_{st} \cup C_{\text{new}}, (\Gamma \times Q') \cup \{\text{bad, } T\}, \Delta', \mathcal{F}')$$

The set $Q'$ of states consists of triples of the form $(q, O, H)$ such that $q$ is a state of $A$, $O$ is an obligation set, and $H$ is a check set, while the set $Q_0'$ of initial states consists of states of the form $(q_0, \emptyset, H)$ such that $q_0 \in Q_0$ (initially there are no obligations).

We now define the transition function $\Delta'$. For this, we first define a predicate $\text{Abs}$ over tuples of the form $((O, H), a, y^*_b \in I, \text{Res}, (O', H'))$ where $(O, H), (O', H')$ are pairs of obligation sets and check sets, $a \in \Sigma$, $y^*_b \in I$ is a constraint of $A$.
involving $y^i_b$, and $Res \subseteq C_{\text{new}}$. Intuitively, $O$ (resp., $H$) represents the obligation set (resp., check set) at the current position $i$ of the input, $a$ is the input symbol associated with position $i$, $y^j_b \in I$ is the prediction about $y^i_b$ done by $A$ at position $i$, $Res$ is the set of new standard clocks reset by $A_{y^i_b}$ on reading $a$, and $O'$ (resp., $H'$) represents the obligation set (resp., check set) at the position $j$ following $i$ along the MAP visiting $i$ (if $i$ is a call, then $j$ is the matching-return of $i$). Formally, $Abs((O,H),a,y^i_b \in I,\text{Res},(O',H'))$ iff the following holds:

1. $(p_\infty \in H$ iff $p_\infty \in H')$, $a \in \Sigma_{\text{call}}$ (resp., $a \in \Sigma_{\text{ret}}$, resp. $a \in \Sigma_{\text{int}}$) implies call $\in H$ (resp., ret $\in H$, resp., int $\in H$).
2. $F^a b \in H$ iff $(b = a$ or $F^a b \in H')$, and $(F^a b \in H' \text{ iff } I \neq \{\perp\})$.
3. If $I = \{\perp\}$, then $O' = \text{live}(O)$, $Res = \emptyset$, and $b \neq a$ implies $O = \text{live}(O)$.
   Otherwise, let $y^i_b \in I \equiv y^i_b > \ell \land y^i_b < u$. Let $O''$ be $O$ if $b \neq a$, and $O'' = \text{live}(O)$ otherwise. Then, $O' = O'' \cup \{\ell\} \cup \{(f,\prec u)\}$, where $f = \text{live}$ if $(\text{live},\prec u) \in O''$, and $f = \text{first}$ otherwise. Moreover, $Res \subseteq \{z_{\succ \ell},z_{\triangle u}\}$, $z_{\succ \ell} \in Res$, and $z_{\triangle u} \in Res$ iff either $\prec u$ does not appear in $O$, or $b = a$ and $(\text{first},\prec u) \in O$.

Condition 1 requires that the Boolean value of proposition $p_\infty$ is invariant along the positions of a MAP, and the current check set is consistent with the type (call, return, or internal symbol) of the current input symbol. Condition 2 provides the abstract-local propagation rules of formula $F^a b$. Finally, Condition 3 provides the rules for updating the obligations on moving to the abstract next position along the current MAP and for resetting new clocks on reading the current input symbol $a$. Note that if $I = \{\perp\}$ and $b \neq a$, then the current obligation set must contain only live upper-bound obligations. If, instead, $y^i_b \in I$ is equivalent to $y^i_b > \ell \land y^i_b < u$, then the clock $z_{\succ \ell}$ is reset, while the clock $z_{\triangle u}$ is reset iff either there is no obligation $(f,\prec u)$ in $O$, or $b = a$ and the obligation $(f,\prec u)$ is fresh, i.e., $f = \text{first}$.

The transition function $\Delta'$ of $A_{y^i_b}$ is then defined as follows. Recall that we can assume that each clock constraint of $A$ is of the form $\theta \land y^i_b \in I$, where $\theta$ does not contain occurrences of $y^i_b$.

**Push transitions:** for each push transition $q \xrightarrow{a,\theta \land y^i_b \in I,\text{Push}(\gamma)} q'$ of $A$, we have the push transitions $(q,O,H) \xrightarrow{a,\theta \land \text{con}(O,a),\text{Push}(\gamma)} (q',O',H')$ such that $b = a$ iff $b \in H$, and

1. Case $\gamma' \neq \text{bad}$: Then, $\gamma' = (\gamma,\text{Push}(\gamma),H_{\text{ret}})$ and $\text{Abs}(O,H),a,y^i_b \in I,\text{Push}(\gamma),(O_{\text{ret}},H_{\text{ret}}))$. Moreover, if $\text{ret} \in H'$ then $H_{\text{ret}} = H'$ and $O' = O_{\text{ret}}$; otherwise, $p_\infty \notin H'$ and $O'$ consists of the live obligations $(\text{live},\prec u)$ such that $(f,\prec u) \in O_{\text{ret}}$ for some $f \in \{\text{live,first}\}$.
2. Case $\gamma' = \text{bad}$: call $\text{in} H$, $I = \{\perp\}$, $(F^a b \in H$ iff $b = a)$, $p_\infty \in H$, $p_\infty \in H'$, ret $\notin H'$, $O' = \emptyset$, $Res' = \emptyset$, and $b \neq a$ implies $O = \emptyset$.

Note that if $b = a$, the obligations in the current state are checked by the constraint on $C_{\text{new}}$ given by $\text{con}(O,a)$ (recall that if $b \neq a$, then $\text{con}(O,a) = \text{true}$). The push transitions of point 1 consider the case where $A_{y^i_b}$ guesses
that the current call position \(i_c\) has a matching return \(i_r\). In this case, the set of obligations and the check state for the next abstract position \(i_r\) along the current MAP are pushed on the stack in order to be recovered at the matching-return \(i_r\). Moreover, if \(A_{v_b}^γ\)1 guesses that the next position \(i_c+1\) is not \(i_r\) (i.e., \(\text{ret} \notin H'\)), then all the upper-bound obligations in \(O_{\text{ret}}\) are propagated as live obligations at the next position \(i_c+1\) (note that the MAP visiting \(i_c+1\) starts at \(i_c+1\), terminates at \(i_r-1\), and does not satisfy proposition \(p_∞\)). The push transitions of point 2 consider instead the case where \(A_{v_b}^γ\) guesses that the current call position \(i_c\) has no matching return \(i_r\), i.e., \(i_c\) is the last position of the current MAP. In this case, \(A_{v_b}^γ\) pushes the symbol \textit{bad} on the stack and the transition relation is consistently updated.

\[\text{Internal transitions:} \text{ for each internal transition } q \xrightarrow{a,θ^γ∈L,\text{Res}} q' \text{ of } A, \text{ we add the internal transitions } (q, O, H) \xrightarrow{a,θ^γ,\text{con}(O,a),\text{Res}} (q', O', H'), \text{ where } b = a \text{ iff } b ∈ H, \text{ and}
\]

1. Case \(\text{ret} ∈ H': \text{int} ∈ H, I = \{⊥\}, \text{Res}' = ∅, (\text{F}b \in H \text{ iff } b = a), \text{ and } b ≠ a \text{ implies } O = \text{live}(O).
2. Case \(\text{ret} \notin H': \text{Abs}((O, H), a, y_b^γ \in I, \text{Res}'((O', H'))).

In the first case, \(A_{v_b}^γ\) guesses that the current internal position \(i\) is the last one of the current MAP(\text{ret} ∈ H'), while in the second case the current MAP visits the next non-return position \(i+1\). Note that if \(b = a\), the obligations in the current state are checked by the constraint \text{con}(O,a).

\[\text{Pop transitions:} \text{ for each pop transition } q \xrightarrow{a,θ^γ∈L,\text{Res},\text{pop}(γ)} q' \notin Δ_r, \text{ we have the pop transitions } (q, O, H) \xrightarrow{a,θ^γ,\text{con}(O,a),\text{Res},\text{pop}(γ')} (q', O', H'), \text{ where } b = a \text{ iff } b ∈ H, \text{ and}
\]

1. Case \(γ ≠ ⊤\): \(\text{ret} ∈ H\) and \(γ' = (γ, (O, H))\). If \(\text{ret} \notin H'\), then \(\text{Abs}((O, H), a, y_b^γ \in I, \text{Res}'((O', H'))\); otherwise, \(I = \{⊥\}, \text{Res}' = ∅, (\text{F}b \in H \text{ iff } b = a), \text{ and } b ≠ a \text{ implies } O = \text{live}(O).
2. Case \(γ = ⊤\): \(\text{ret} ∈ H, O = ∅, γ' = ⊤, p_∞ \in H, \text{ and } p_∞ \in H'. \text{ If } \text{ret} \notin H', \text{ then } \text{Abs}((O, H), a, y_b^γ \in I, \text{Res}'((O', H'))\); otherwise, \(I = \{⊥\}, \text{Res}' = ∅, O' = ∅, \text{ and } (\text{F}b \in H \text{ iff } b = a).

If \(γ ≠ ⊤\), then the current return position has a matched-call. Thus, \(A_{v_b}^γ\) pops from the stack \(γ\) together with an obligation set and a check set, and verifies that the last two sets correspond to the ones associated with the current control state. If \(γ = ⊤\), then the current position is also the initial position of the associated MAP.

Finally, the generalized Büchi condition \(F'\) of \(A_{v_b}^γ\) is defined as follows. For each Büchi component \(F\) of \(A, A_{v_b}^γ\) has the Büchi component consisting of the states \((q, O, H)\) such that \(q ∈ F\). Moreover, \(A_{v_b}^γ\) has an additional component consisting of the states \((q, O, H)\) such that \(p_∞ ∈ H\), and either \(\text{F}b \notin H\) or \(b ∈ H\). Such a component ensures that the guesses about the matched calls are
correct ($p_\infty$ occurs infinitely often), and that the liveness requirement $b$ of $F^b$ is fulfilled whenever $F^b$ is asserted at a position of an infinite MAP. Recall that in an infinite word over $\Sigma$, there are at most one infinite MAP $\nu$ and $\nu$ visits only positions where $p_\infty$ holds; moreover, each position $i$ greatest than the initial position $i_0$ of $\nu$ is either a $\nu$-position, or a position where $p_\infty$ does not hold. If an infinite word has no infinite MAP, then $p_\infty$ holds at infinitely many positions as well.

D Removal of abstract recorder clocks in nested VPTA

In this section, we establish the following result.

**Theorem 6 (Removal of abstract recorder clocks).** Given a generalized Büchi nested VPTA $A$ with set of event clocks $C$ and an abstract recorder clock $x_b^\nu \in C$, one can construct in singly exponential time a generalized Büchi nested VPTA $A_{x_b}^\nu$ with set of event clocks $C \setminus \{x_b^\nu\}$ such that $L_A = L(A_{x_b}^\nu)$ and $K_{A_{x_b}} = K_A$. Moreover, $A_{x_b}^\nu$ has $O(n \cdot 2^{O(p)})$ states and $m + O(p)$ clocks, where $n$ is the number of $A$-states, $m$ is the number of standard $A$-clocks, and $p$ is the number of event-clock atomic constraints on $x_b^\nu$ used by $A$.

In the following, we illustrate the proof of Theorem 6. Fix a generalized Büchi nested VPTA $A = (\Sigma, Q, Q_0, C \cup C_{st}, I \cup \{\top\}, \Delta, F)$ such that $x_b^\nu \in C$. We can assume that for each transition $\delta$ of $A$, there is exactly one atomic constraint $x_b^\nu \in I$ on $x_b^\nu$ used as conjunct in the clock constraint of $\delta$. We construct a generalized Büchi nested VPTA $A_{x_b}^\nu$ equivalent to $A$ whose set of event clocks is $C \setminus \{x_b^\nu\}$, and whose set of standard clocks is $C_{st} \cup C_{new}$, where $C_{new}$ consists of the fresh standard clocks $z_{\ell_{min}}$ (resp., $z_{\ell_{max}}$) for each lower-bound constraint $x_b^\nu \geq \ell$ (resp., upper-bound constraint $x_b^\nu < u$) of $A$ involving $x_b^\nu$.

We first explain the basic ideas of the translation. Note that a global recorder clock $x_b^\nu$ can be trivially converted in a standard clock by resetting it whenever $b$ occurs along the input word. This approach is not correct for the abstract recorder clock $x_b^\nu$, since along a MAP $\nu$, there may be consecutive positions $i_\nu$ and $i_\nu$ such that $i_\nu$ is a call with matching return $i_r$, and $b$ may occur along positions in $[i_\nu + 1, i_r - 1]$ which are associated with MAP distinct from $\nu$. Thus, as in the case of the abstract predictor clock $y_b^\nu$, we replace $x_b^\nu$ with the set $C_{new}$ of fresh standard clocks defined above. For a given infinite word $\sigma$ over $\Sigma$, a MAP $\nu$ of $\sigma$ and a position $i$ of $\nu$, we denote by $infix_\nu(\nu, i)$ the infix of $\nu$ defined as follows: if there exists the smallest $b$-position $j > i$ visited by $\nu$, then $infix_\nu(\nu, i)$ is the infix of $\nu$ between the next position of $i$ along $\nu$ and the position $j$; otherwise, $infix_\nu(\nu, i)$ is the suffix of $\nu$ starting from the next position of $i$ along $\nu$ (note that in this case $infix_\nu(\nu, i)$ is empty if $i$ is the last position of $\nu$). The main idea of the construction is that when $b$ occurs at the current position $i$ of the input word, the simulating automaton $A_{x_b}^\nu$ guesses the set of lower-bound and upper-bound constraints on $x_b^\nu$ which will be used by $A$ along the portion $infix_\nu(\nu, i)$ of the current MAP.
First, let us consider lower-bound constraints $x_b^i \succ \ell$. Assume that $b$ occurs at position $i$ of the input word for the first time and that $i$ is not the last position of the current MAP $\nu$ (hence, $\text{infix}_\nu(\nu, i)$ is not empty). Then, $A_{x_b^i}$ guesses the set of lower-bound constraints $x_b^i \succ \ell$ which will be used by $A$ along $\text{infix}_\nu(\nu, i)$. For each of such guessed constraints $x_b^i \succ \ell$, the associated new clock $z_{\succ \ell}$ is reset; moreover, if $i$ is not a call (resp., it is a call), $A_{x_b^i}$ carries the obligation $\succ \ell$ in its control state (resp., pushes the obligation $\succ \ell$ onto the stack). On visiting the positions $j$ in $\text{infix}_\nu(\nu, i)$, $A_{x_b^i}$ checks that the guess is correct by verifying that for the current lower-bound constraint $x_b^i \succ \ell$ used by $A$, $\succ \ell'$ is in the current set of obligations, and constraint $z_{\succ \ell} \succ \ell'$ holds. Moreover, at position $j$, $A_{x_b^i}$ guesses whether the constraint $x_b^i \succ \ell'$ will be again used along $\text{infix}_\nu(\nu, i)$, or not. In the first case, the obligation $\succ \ell'$ is kept, otherwise, it is discarded. The crucial observation is that:

- If a call $i_c \geq i$ occurs along $\nu$ before the last position (if any) of $\text{infix}_\nu(\nu, i)$, we know that the next position of $i_c$ along $\nu$ is the matching return $i_r$ of $i_c$, $i_r$ is visited by $\text{infix}_\nu(\nu, i)$, and all the MAP visiting positions $h \in [i_c + 1, i_r - 1]$ are finite and terminate at positions $k < i_r$. Thus, the fulfillment of a lower-bound constraint $x_b^i \succ \ell$ asserted at a position of such MAP always implies the fulfillment of the same constraint when asserted at a position $j \geq i_r$ of $\text{infix}_\nu(\nu, i)$. Thus, at the time of a guess (i.e., when a $b$ occurs) along a MAP visiting positions in $[i_c + 1, i_r - 1]$, the clocks $z_{\succ \ell}$ associated with the guessed lower-bound constraints $x_b^i \succ \ell$ can be safely reset.

At each position $i$, $A_{x_b^i}$ keeps track in its control state of the lower-bound obligations for the part $\text{infix}_\nu(\nu, i)$ of the current MAP $\nu$. Whenever a call $i_c$ occurs, the guessed lower-bound obligations for the matching return $i_r$ of $i_c$ are pushed on the stack in order to be recovered at position $i_r$. Moreover, if $i_c + 1$ is not a return (i.e., $i_r \neq i_c + 1$), then $A_{x_b^i}$ moves to a control state where the set of lower-bound obligations is empty (consistently with the fact that $i_c + 1$ is the initial position of the MAP visiting $i_c + 1$).

The case for upper-bound constraints $x_b^i \prec u$ is symmetric. Whenever $b$ occurs at a position $i$ of the input word which is not the last position of the current MAP $\nu$ and $A_{x_b^i}$ guesses that the constraint $x_b^i \prec u$ will be used by $A$ along the infix $\text{infix}_\nu(\nu, i)$, then, assuming that no obligation is currently associated to the constraint $x_b^i \prec u$, $A_{x_b^i}$ resets the standard clock $z_{\prec u}$ and carries the fresh obligation $(\text{first}, \prec u)$ in its control state (resp., pushes the obligation $(\text{first}, \prec u)$ onto the stack) if $i$ is not a call (resp., it is a call). When at a position $j$ of the infix $\text{infix}_\nu(\nu, i)$, $A$ uses the constraint $x_b^i \prec u$, $A_{x_b^i}$ checks that $(\text{first}, \prec u)$ is in the current set of obligations, and that the constraint $z_{\prec u} \prec u$ holds. The obligation $(\text{first}, \prec u)$ is removed or confirmed, depending on whether $A_{x_b^i}$ guesses that $x_b^i \prec u$ will be again used by $A$ along $\text{infix}_\nu(\nu, i)$ or not. Assume now that a call position $i_c \geq i$ occurs along $\nu$ before the last position (if any) of $\text{infix}_\nu(\nu, i)$, and let $i_r$ be the matching return of $i_c$. The important observation is that:

- the fulfillment of an upper-bound constraint $x_b^i \prec u$ asserted at a position $j \geq i_r$ of $\text{infix}_\nu(\nu, i)$ always implies the fulfillment of the same constraint when asserted at a position $h$ of a MAP $\nu'$ visiting positions in $[i_c + 1, i_r - 1]$.
such that $h$ is preceded along $\nu'$ by a position where $b$ occurs. Thus, if the constraint $x^b_i < u$ is guessed to hold at a position $j \geq i_\nu$ of $\text{infix}_\nu(\nu, i)$, for the guesses on the constraint $x^b_i < u$ done by $A_{x^b_i}$ along the positions in $[i_\nu + 1, i_\nu - 1]$, the clock $z_{<u}$ is not reset at the times of the guesses (i.e., when $b$ occurs along the positions in $[i_\nu + 1, i_\nu - 1]$).

Whenever a call $i_\nu$ occurs, the updated set $O$ of upper-bound and lower-bounds obligations is pushed onto the stack in order to be recovered at the matching return $i_\nu$ of $i_\nu$. Moreover, if $i_\nu + 1$ is not a return (i.e., $i_\nu \neq i_\nu + 1$), then $A_{x^b_i}$ moves to a control state where, while the set of lower-bound obligations is empty, the set of upper-bound obligations is obtained from $O$ by replacing each upper-bound obligation $(f, <u)$, where $f \in \{\text{live}, \text{first}\}$ with the live obligation $(\text{live}, <u)$. A live obligation $(\text{live}, <u)$ asserted at the initial position $i_\nu + 1$ of the MAP $\nu$ visiting $i_\nu + 1$ (note that $\nu$ terminates at position $i_\nu - 1$) is used by $A_{x^b_i}$ to remind that the clock $z_{<u}$ cannot be reset along $\nu$ when $b$ occurs. Intuitively, live upper-bound obligations are propagated from the caller MAP to the called MAP. Note that fresh upper-bound obligations $(\text{first}, <u)$ always refer to guesses done along the current MAP and differently from the live upper-bound obligations, may be removed, when along the current MAP, they are checked.

There are other technical issues to be handled. As for the construction associated to the automaton $A_{y^f_i}$ for an abstract predictor clock $y^f_i$, the automaton $A_{x^b_i}$ uses the special proposition $p_{\infty}$, and keeps track in its control state of the guessed type (call, return, or internal symbol) of the next input symbol in order to check whether the current input position is the last one of the current MAP. Moreover, we have to ensure that the lower-bound obligations $\succ \ell$ (resp., the fresh upper-bound obligations $(\text{first}, <u)$) at the current position $i$ are eventually checked, i.e., for the current MAP $\nu$, $\text{infix}_\nu(\nu, i)$ eventually visits a position $j$ where the constraint $x^b_i \succ \ell$ (resp., $x^b_i < u$) is used. For this, $A_{x^b_i}$ keeps track in its control state of the guessed interval constraint $x^b_i \in I$ used by $A$ on reading the next input symbol, and whether the guessed next input symbol is $b$. Moreover, for each lower-bound obligation $\succ \ell$ (resp., fresh upper-bound obligations $(\text{first}, <u)$), $A_{x^b_i}$ exploits a B"uchi component ensuring that along an infinite MAP $\nu$, either there are infinitely many occurrences of $b$-positions, or there are infinitely many occurrences of positions where an interval constraint $x^b_i \in I$ consistent with $x^b_i \succ \ell$ (resp., $x^b_i < u$) is used, or there are infinitely many positions in $\nu$ where the set of obligations does not contain $\succ \ell$ (resp., $(\text{first}, <u)$).

We now provide the formal definition of $A_{x^b_i}$. To this end, we need additional notation. An obligation set $O$ (for the fixed recorder event $x^b_i$) is a set consisting of lower-bound obligations $\succ \ell$ and upper-bound obligations $(f, <u)$, where $f \in \{\text{live}, \text{first}\}$, such that $x^b_i \succ \ell$ and $x^b_i < u$ are associated to interval constraints $x^b_i \in I$ of $A$, and $(f, <u), (f', <u) \in O$ implies $f = f'$. For an obligation set $O$, $\text{live}(O)$ consists of the live upper-bound obligations of $O$. Given an obligation set $O$ and an interval constraint $x^b_i \in I$ of $A$, we say that $x^b_i \in I$ is consistent with $O$ if one of the following holds:

- $I = \{\bot\}$ and $O = \text{live}(O)$.
- $x^b_i \in I \equiv x^b_i \succ \ell \land x^b_i < u, \succ \ell \in O$ and $(f, <u) \in O$ for some $f \in \{\text{first}, \text{live}\}$.
Let $\Phi(x^*_b)$ be the set of interval constraints of the form $x^*_b \in I$ used by $A$. A check set $H$ is a subset of $\{\text{call, ret, int, } p_{\infty}, b\} \cup \Phi(x^*_b)$ such that $H \cap \{\text{call, ret, int}\}$ and $H \cap \Phi(x^*_b)$ are singletons. We say that $H$ and an obligation set $O$ are consistent if the unique interval constraint in $H$ is consistent with $O$. For an interval constraint $x^*_b \in I$ used by $A$, let $con(I)$ be the constraint over $C_{\text{new}}$ defined as follows: $con(I) = \text{true}$ if $I = \{\bot\}$, and $con(I) = z_{>\ell} \succ \ell \land z_{<u} < u$ if $x^*_b \in I \equiv x^*_b \succ \ell \land x^*_b \prec u$. The nested VPTA $A_{x^*_b}$ is given by

$$A_{x^*_b} = (\Sigma, Q', Q'_0, C \setminus \{x^*_b\} \cup C_{\text{std}} \cup C_{\text{new}}, (I \times Q') \cup \{\text{bad, } \top\}, \Delta', F')$$

where the set $Q'$ of states consists of triples of the form $(q, O, H)$ such that $q$ is a state of $A$, $O$ is an obligation set, $H$ is a check set, and $H$ and $O$ are consistent. The set $Q'_0$ of initial states consists of states of the form $(q_0, \emptyset, H)$ such that $q_0 \in Q_0$ (initially there are no obligations). Note that for an initial state $(q_0, \emptyset, H)$, $(x^*_b \in \{\bot\}) \in H$ ($H$ and the obligation set $\emptyset$ are consistent).

We now define the transition function $\Delta'$. To this end, we first define a predicate $\text{AbsP}$ over tuples of the form $((O, H), a, x^*_b \in I, Res, (O', H'))$ where $(O, H), (O', H')$ are pairs of obligation sets and check sets, $a \in \Sigma$, $x^*_b \in I$ is a constraint of $A$, and $Res \subseteq C_{\text{new}}$. Intuitively, $O$ (resp., $H$) represents the obligation set (resp., check set) at the current position $i$ of the input, $a$ is the input symbol associated with position $i$, $x^*_b \in I$ is the constraint on $x^*_b$ used by $A$ at position $i$, $Res$ is the set of new standard clocks reset by $A$ on reading $a$, and $O'$ (resp., $H'$) represents the obligation set (resp., check set) at the position $j$ following $i$ along the MAP visiting $i$ (if $i$ is a call, then $j$ is the matching-return of $i$). Formally, $\text{AbsP}(O, H), a, x^*_b \in I, Res, (O', H'))$ is true if the following holds:

1. $(p_{\infty} \in H \iff p_{\infty} \in H')$, $a \in \Sigma_{\text{call}}$ (resp., $a \in \Sigma_{\text{ret}}$, resp. $a \in \Sigma_{\text{int}}$) implies $\text{call} \in H$ (resp., $\text{ret} \in H$, resp., $\text{int} \in H$).
2. $(x^*_b \in I) \in H$, and $H$ and $O$ are consistent (resp., $H'$ and $O'$ are consistent).
3. Case $b = a$: $b \in H$, $(x^*_b \in \{\bot\}) \notin H'$ and $Res$ is a subset of $C_{\text{new}}$ such that $z_{<u} \in Res$ implies $(\text{live}, z_{<u}) \notin O$. Moreover, $O' = \text{live}(O) \cup O''$, where $O''$ is obtained from $Res$ by adding for each clock $z_{>\ell} \in Res$ (resp., $z_{<u} \in Res$), the obligation $\succ \ell$ (resp., the fresh obligation $(\text{first}, z_{<u})$).
4. Case $b \neq a$: $b \notin H$, $Res = \emptyset$. If $I = \{\bot\}$, then $O' = O = \text{live}(O)$ and $(x^*_b \in \{\bot\}) \in H'$. Otherwise, let $x^*_b \in I \equiv x^*_b \succ \ell \land x^*_b \prec u$. Then, $(x^*_b \notin \{\bot\}) \in H'$, and $O'$ is any obligation set obtained from $O$ by optionally removing the obligation $\succ \ell$ (by Condition 2, $\succ \ell \in O$), and/or by optionally removing the obligation $(\text{first}, z_{<u})$ if $(\text{first}, z_{<u}) \in O$.

Condition 1 requires that the Boolean value of proposition $p_{\infty}$ is invariant along the positions of a MAP, and the current check set is consistent with the type (call, return, or internal symbol) of the current input symbol. Condition 2 requires that the current check set is consistent with the constraint $x^*_b \in I$ currently used by $A$. Conditions 3 and 4 provide the rules for updating the obligations on moving to the abstract next position along the current MAP and for resetting new clocks on reading the current input symbol $a$. Note that if $I = \{\bot\}$ and $b \neq a$, then the current obligation set must contain only live upper-bound obligations, and $(x^*_b \in \{\bot\}) \in H'$. 
Given a state \((q, O, H)\) of \(A_{\mathcal{x}_b^*}\), we say that \((q, O, H)\) is terminal if the following holds: if \(x_b^* \in I\) is the unique constraint associated with the check set \(H\) and \(x_b^* \in I \equiv x_b^* \not> \ell \wedge x_b^* \not< u\), then \(O \setminus \{\not> \ell, \not< u\} = \text{live}(O)\). Intuitively, terminal states are associated with input positions \(i\) such that \(i\) is the last position of the related MAP.

The transition function \(\Delta'\) of \(A_{\mathcal{x}_b^*}\) is then defined as follows. Recall that we can assume that each clock constraint of \(A\) is of the form \(\theta \land x_b^* \in I\), where \(\theta\) does not contain occurrences of \(x_b^*\).

**Push transitions:** for each push transition \(q \xrightarrow{a, \theta \land x_b^* \in I, \text{Res}, \text{push}(\gamma)} q'\) of \(A\), we have the push transitions \((q, O, H) \xrightarrow{a, \theta \land \text{con}(I), \text{Res} \cup \text{Res}', \text{push}(\gamma)} (q', O', H')\) such that \(b \in H\) if \(a = b\), and

1. Case \(\gamma' \neq \text{bad}\). Then, \(\gamma' = (\gamma, \text{O}_\text{ret}, H_{\text{ret}})\) and
   - \(\text{AbsP}((O, H), a, x_b^* \in I, \text{Res} \cup \text{Res}', (O_{\text{ret}}, H_{\text{ret}}))\). Moreover, if \(\text{ret} \in H'\) then \(H' = H'\) and \(O' = O_{\text{ret}}\); otherwise, \(p_{\infty} \not\in H'\) and \(O'\) consists of the live obligations \((\text{live}, \not<u)\) such that \((f, \not<u) \in O_{\text{ret}}\) for some \(f \in \{\text{live}, \text{first}\}\).
2. Case \(\gamma' = \text{bad}: \text{call} \in H, (x_b^* \in I) \in H, \text{state} (q, O, H)\) is terminal, \(p_{\infty} \in H, p_{\infty} \in H', \text{ret} \not\in H', O' = \emptyset\), and \(\text{Res}' = \emptyset\).

Note that if \(I \neq \{\bot\}\), then the constraint \(x_b^* \in I\) is checked by the constraint \(\text{con}(I)\) (recall that if \(I = \{\bot\}\), then \(\text{con}(I) = \text{true}\) ). The push transitions of point 1 consider the case where \(A_{\mathcal{x}_b^*}\) guesses that the current call position \(i_c\) has a matching return \(i_r\). In this case, the set of obligations and the check state for the next abstract position \(i_{c+1}\) along the current MAP are pushed on the stack in order to be recovered at the matching-return \(i_r\). Moreover, if \(A_{\mathcal{x}_b^*}\) guesses that the next position \(i_{c+1}\) is not \(i_r\) (i.e., \(\text{ret} \not\in H'\)), then all the upper-bound obligations in \(O_{\text{ret}}\) are propagated as live obligations at the next position \(i_{c+1}\) (note that the MAP visiting \(i_{c+1}\) starts at \(i_{c+1}\), terminates at \(i_{r-1}\), and does not satisfy proposition \(p_{\infty}\)). The push transitions of point 2 consider instead the case where \(A_{\mathcal{x}_b^*}\) guesses that the current call position \(i_c\) has no matching return \(i_r\), i.e., \(i_c\) is the last position of the current MAP. In this case, \(A_{\mathcal{x}_b^*}\) pushes the symbol \(\text{bad}\) on the stack and the transition relation is consistently updated.

**Internal transitions:** for each internal transition \(q \xrightarrow{a, \theta \land x_b^* \in I, \text{Res}} q'\) of \(A\), we add the internal transitions \((q, O, H) \xrightarrow{a, \theta \land \text{con}(I), \text{Res} \cup \text{Res}', (O', H')} (q', O', H')\) such that \(b \in H\) if \(a = b\), and

1. Case \(\text{ret} \in H'\): \(\text{int} \in H, (x_b^* \in I) \in H, \text{state} (q, O, H)\) is terminal, and \(\text{Res}' = \emptyset\).
2. Case \(\text{ret} \not\in H'\): \(\text{AbsP}((O, H), a, x_b^* \in I, \text{Res}', (O', H'))\).

In the first case, \(A_{\mathcal{x}_b^*}\) guesses that the current internal position \(i\) is the last one of the current MAP (\(\text{ret} \in H'\)), while in the second case the current MAP visits the next non-return position \(i_r = i + 1\).
Pop transitions: for each pop transition \( q \xrightarrow{a, \theta \land x_b^l \in I, \text{Res}, \text{pop}(\gamma)} q' \in \Delta_c \), we have the pop transitions \( (q, O, H) \xrightarrow{a, \theta \land \text{con}(I), \text{Res}, \text{pop}(\gamma')} (q', O', H') \) such that \( b \in H \) iff \( a = b \), and

1. Case \( \gamma \neq \top \): \( \text{ret} \in H \), \( \gamma' = (\gamma, (O, H)) \), and \( (x_b^a \in I) \in H \). If \( \text{ret} \notin H' \), then AbsP\((O, H), a, x_b^a \in I, \text{Res}', (O', H')\); otherwise, \((q, O, H)\) is a terminal state and \( \text{Res}' = \emptyset \).

2. Case \( \gamma = \top \): \( \text{ret} \in H \), \( I = \{ \bot \} \), \( \gamma' = \top \), \( p_{\infty} \in H \), \( p_{\infty} \in H' \), and \( O = \emptyset \). If \( \text{ret} \notin H' \), then AbsP\((O, H), a, x_b^a \in I, \text{Res}', (O', H')\); otherwise, \( \text{Res}' = \emptyset \) and \( O' = \emptyset \).

If \( \gamma \neq \top \), then the current return position has a matched-call. Otherwise, the current position is also the initial position of the associated MAP.

Finally, the generalized Büchi condition \( F' \) of \( A_{x_b^a} \) is defined as follows. For each Büchi component \( F \) of \( A \), \( A_{x_b^a} \) has the Büchi component consisting of the states \((q, O, H)\) such that \( q \in F \). Moreover, \( A_{x_b^a} \) has an additional component consisting of the states \((q, O, H)\) such that \( p_{\infty} \in H \). Such a component ensures that the guesses about the matched calls are correct. Finally, for each lower-bound constraint \( x_b^a > \ell \) (resp., upper-bound constraint \( x_b^a < u \)) of \( A \), \( A_{x_b^a} \) has a Büchi component consisting of the states \((q, O, H)\) such that

- \( p_{\infty} \in H \), and either \( b \in H \), or the unique constraint in \( H \) is equivalent to \( x_b^a > \ell \land x_b^a < u' \) for some upper-bound \( u' \), or \( \ell \notin O \);
- \( (r_{\infty}, p_{\infty}) \in H \), and either \( b \in H \), or the unique constraint in \( H \) is equivalent to \( x_b^a > \ell \land x_b^a < u \) for some lower-bound \( \ell' \), or \((\text{first}, \prec u) \notin O \).

Thus, the above Büchi component ensures that along an infinite MAP \( \nu \), either there are infinitely many occurrences of \( b \)-positions, or there are infinitely many occurrences of positions where an interval constraint \( x_b^a \in I \) consistent with \( x_b^a > \ell \) (resp., \( x_b^a < u \)) is used, or there are infinitely many positions in \( \nu \) where the set of obligations does not contain \( \succ \ell \) (resp., \( \prec u \)).

E Removal of caller event-clocks in nested VPTA

In this section, we prove the following result.

Theorem 7 (Removal of caller event-clocks). Given a generalized Büchi nested VPTA \( \mathcal{A} \) with set of event clocks \( C \) and a caller event-clock \( x_b^a \in C \), one can construct in singly exponential time a generalized Büchi nested VPTA \( \mathcal{A}_{x_b^a} \) with set of event clocks \( C \setminus \{ x_b^a \} \) such that \( \mathcal{L}_T(\mathcal{A}_{x_b^a}) = \mathcal{L}_T(\mathcal{A}) \) and \( K_{\mathcal{A}_{x_b^a}} = K_\mathcal{A} \).

Moreover, \( \mathcal{A}_{x_b^a} \) has \( O(n \cdot 2^{O(p)}) \) states and \( m + O(p) \) clocks, where \( n \) is the number of \( \mathcal{A} \)-states, \( m \) is the number of standard \( \mathcal{A} \)-clocks, and \( p \) is the number of event-clock atomic constraints on \( x_b^a \) used by \( \mathcal{A} \).

Fix a generalized Büchi nested VPTA \( \mathcal{A} = (\Sigma, Q, Q_0, C \cup C_{st}, \Gamma \cup \{ \top \}, \Delta, F) \) such that \( x_b^a \in C \). We construct a generalized Büchi nested VPTA \( \mathcal{A}_{x_b^a} \) equivalent to \( \mathcal{A} \) whose set of event clocks is \( C \setminus \{ x_b^a \} \), and whose set of standard clocks is \( C_{st} \cup C_{new} \), where \( C_{new} \) consists of the fresh standard clocks \( z_{\succ \ell} \) (resp., \( z_{\prec u} \)).
for each lower-bound constraint $x^c_b \succ \ell$ (resp., upper-bound constraint $x^u_b < u$) of $A$ involving $x_b^c$. Since a caller path from a position $j$ consists only of call positions except position $j$ (if $j \notin \Sigma_{call}$), we assume that $b \in \Sigma_{call}$ (the case where $b \notin \Sigma_{call}$ is straightforward).

The main idea of the construction is that whenever $b$ occurs at a call position $i_c$ of the input word, the simulating automaton $A_{x_b^c}$ guesses the set of lower-bound and upper-bound constraints on $x_b^c$ that will be used by $A$ along the MAP $\nu$ having $i_c$ as caller. Note that such a MAP is empty if $i_c + 1$ is a return, and starts at position $i_c + 1$ otherwise.

First, let us consider lower-bound constraints $x_b^c \succ \ell$. Assume that $b$ occurs at a call position $i_c$ of the input word and $i_c + 1$ is not a return. Let $\nu$ be the MAP starting at position $i_c + 1$. Then, $A_{x_b^c}$ guesses the set of lower-bound constraints $x_b^c \succ \ell$ that will be used by $A$ along $\nu$. For each of such guessed constraints $x_b^c \succ \ell$, $A_{x_b^c}$ resets the associated new clock $z \succ \ell$, and moves to the next position by carrying in the control state the new set of lower-bound obligations $\succ \ell$. On visiting the positions $j$ of $\nu$, $A_{x_b^c}$ checks that the guess is correct by verifying that for the current lower-bound constraint $x_b^c \succ \ell'$ used by $A$, $\succ \ell'$ is in the current set of obligations, and constraint $z \succ \ell' \succ \ell'$. Moreover, at position $j$, $A_{x_b^c}$ guesses whether the constraint $x_b^c \succ \ell$ will be again used along $\nu$, or not. In the first case, the obligation $\succ \ell'$ is kept, otherwise, it is discarded. If a new call $n_c$ occurs along $\nu$ before the last position of $\nu$, then all the caller paths starting from the positions $h \in [n_c + 1, n_r - 1]$, where $n_r$ is the matching return of $n_c$ (i.e., $n_r$ is the position following $n_c$ along $\nu$), visit positions $i_c$ and $n_c$ ($n_c > i_c$).

Thus, the fulfillment of a lower-bound constraint $x_b^c \succ \ell$ asserted at a position $h \in [n_c + 1, n_r - 1]$ always implies the fulfillment of the same constraint when asserted at a position $j \geq i_r$ of $\nu$. Therefore, if $b$ occurs at the new call-position $n_c$, the clocks $z \succ \ell$ associated with the guessed lower-bound constraints $x_b^c \succ \ell$ used by $A$ along the MAP having $n_c$ as caller (such a MAP starts at position $n_c + 1$ and leads to position $n_r - 1$) can be safely reset.

Overall, at each position $i$, $A_{x_b^c}$ keeps track in its control state whether the caller path from $i$ visits a $b$-position preceding $i$, or not. In the first case, $A_{x_b^c}$ also keeps track in its control state of the set of obligations associated with the guessed lower-bound constraints on $x_b^c$ which will be used by $A$ in the suffix of the current MAP from position $i$. In the second case, there are no obligations. Whenever a matched call $i_c \geq i$ occurs along $\nu$, the guessed lower-bound obligations (if any) for the matching return $i_r$ of $i_c$ are pushed on the stack in order to be recovered at position $i_r$. Moreover, if $i_c + 1$ is not a return (i.e., $i_c \neq i_c + 1$), and either we are in the first case or $i_c$ is a $b$-position, then $A_{x_b^c}$ guesses the set $L$ of lower-bound constraints which will be used by $A$ in the finite MAP starting at position $i_c + 1$, and moves to the next position by carrying in its control state the obligations associated with $L$. Additionally, if $i_c$ is a $b$-position, then for each $x_b^c \succ \ell \in L$, the associated new clock $z \succ \ell$ is reset.

The situation for upper-bound constraints $x_b^c < u$ is dual. In this case, as in the proof of Theorem [4] we distinguish between fresh upper-bound obligations (first, $< u$) and live upper-bound obligations (live, $< u$). Fresh upper-bound
obligations \((\text{first}, \prec u)\) always refer to guesses done along the current \(MAP\) and differently from the live upper-bound obligations, may be removed, when along the current \(MAP\), they are checked. Live upper-bound obligations \((\text{live}, \prec u)\) are propagated from the caller \(MAP\) to the called \(MAP\). They are used by \(A_{\omega_b}\) to remember that at a matched \(b\)-call position \(i_c\) along the current \(MAP\) with matching return \(i_r > i_c + 1\), if the upper-bound constraint \(x_b \prec u\) is guessed to be used by \(A\) along the finite \(MAP\) \(\nu'\) having as caller \(i_c\) \((\nu'\) starts at \(i_c + 1\) and ends at \(i_r - 1\)), and the guessed set of obligations for the matching return \(i_r\) already contains an obligation \((f, \prec u)\), then the clock \(z \prec u\) must not be reset. This is safe since the fulfillment of an upper-bound constraint \(x_b \prec u\) asserted at a position \(j \geq i_r\) along \(\nu\) always implies the fulfillment of the same constraint when asserted at a position \(h\) of the \(MAP\) \(\nu'\).

The formal definition of \(A_{\omega_b}\) is similar to that of the nested VPTA \(A_{\sigma_b}\) exploited in the proof of Theorem \([1]\). Thus, here, we omit the details of the construction.
