Pseudo-Leptomeningeal Contrast Enhancement at 3T in Pediatric Patients Sedated by Propofol

A.M. McKinney, A. Chacko Achanaril, B. Knoll, D.R. Nascene, and R.S. Gawande

ABSTRACT

BACKGROUND AND PURPOSE: Propofol is a cerebral vasoconstrictor that modulates cerebral perfusion by decreasing the metabolic rate of oxygen. Because younger children often undergo intravenous sedation for MR imaging, this study set out to evaluate the degree of leptomeningeal contrast enhancement on 3T postcontrast brain MR imaging and to determine whether this phenomenon relates to sequence, sedation dosage, or patient age or weight.

MATERIALS AND METHODS: During a 2-year period, of 152 children 1–5 years of age who underwent MR imaging, 43 were included for MRI review. Of these, 37 underwent postcontrast imaging with either solely gradient-echo T1WI (n/H11005 20) or spin-echo T1WI (n/H11005 17); notably, 6 patients underwent both sequences. Three neuroradiologists separately graded the degree of leptomeningeal contrast enhancement (grades 0–3) that was correlated with various factors and calculated the interobserver reliability.

RESULTS: For the 43 patients, the mean patient age was 3.1 ± 1.4 years. The leptomeningeal contrast-enhancement grade was significantly greater (P < .0001) on spin-echo T1WI (1.9–2.1) versus gradient-echo T1WI (1.2–1.4). Patient weight (r = −0.366 to −0.418, P = .003–.01) and age (r = −0.315 to −0.418, P = .004–.032) moderately and inversely correlated with the leptomeningeal contrast-enhancement grade, while the propofol dosage, sedation duration, and time to T1WI post-contrast administration did not (each, P > .05). The interobserver κ was strong regarding the leptomeningeal contrast-enhancement grade on both spin-echo T1WI (κ = 0.609–0.693, P < .0001) and gradient-echo T1WI (κ = 0.567–0.698, P < .0001).

CONCLUSIONS: Leptomeningeal contrast enhancement (or “pseudo”-leptomeningeal contrast enhancement) occurs with a greater frequency and degree on 3T postcontrast spin-echo T1WI relative to gradient-echo T1WI in younger children sedated with propofol and should not be mistaken for disease. This phenomenon may be more prominent with lower age or size and may arise from propofol-induced vascular smooth-muscle dilation.

ABBREVIATIONS: GE = gradient-echo; LMCE = leptomeningeal contrast enhancement; SE = spin-echo; TTI = time to postcontrast T1-weighted imaging
the degree of this phenomenon of apparent LMCE (termed here “pseudo”-LMCE) relates to the type of T1WI sequence, time to acquiring postcontrast T1WI, propofol dosage, or various patient demographics.

MATERIALS AND METHODS
This retrospective study was performed after Hennepin County Medical Center, Minneapolis, Minnesota, review board approval. Review of the imaging data base and electronic clinical records yielded 152 healthy pediatric patients between the ages of 1 and 5 years who underwent 3T brain MR imaging and were sedated with intravenous propofol between November 2011 and November 2013. Inclusion criteria were the following: 1) ages were between 1 and 5 years; 2) either axial gradient-echo (GE) T1WI or spin-echo (SE) T1WI was performed; 3) the child received gadolinium-based intravenous contrast; 4) intravenous propofol was used for sedation; 5) the patient had either normal examination findings or only mild, nonacute, and noncongenital abnormalities (eg, <5 white matter foci); and 6) the patient had not had meningitis or other clinical diseases that could cause LMCE. Exclusion criteria consisted of the following: studies performed on a 1.5T magnet, an incomplete MR imaging examination, moderate-to-severe structural abnormalities, or clinical signs of meningitis (Fig 1). Anesthesia was induced via intravenous administration of propofol by a pediatric intensivist, without the use of inhalational anesthetics, akin to sedation methods described previously.7

MR Imaging Technique
All studies were performed on a single 3T MR unit (Intera; Philips Healthcare, Best, the Netherlands), with sedation performed by a pediatric intensivist. The imaging parameters for GE T1WI were a volumetric acquisition of 9.8 ms/4.6 ms/8°/15–20 cm/1 (TR/TE/flip angle/FOV/NEX), a 169 x 169 to 240 × 240 matrix, 1-mm section thickness (0-mm gap), and an acquisition time of approximately 5 minutes; these scans were reconstructed in the axial plane at a section thickness of 3 mm. For SE T1WI, the parameters were 353–734 ms/10 ms/14 –20 cm/1 (TR/TE/FOV/NEX), with a 168 x 132 to 265 × 205 matrix, axial 3-mm thickness (0.3–1.0 mm gap), and an acquisition time of about 5 minutes. We attempted to approximate and coregister the GE T1WI and SE T1WI to each other at the same thickness and level. Axial spin-echo T2WI, FLAIR, and DWI were also performed in each patient; the axial spin-echo T2WI and DWI acquisitions were performed after the intravenous administration of gadolinium-based contrast but prior to the postcontrast GE T1WI or SE T1WI acquisitions, to ensure a minimum delay of several minutes before the T1WI acquisitions were performed. The standard weight-based intravenous dose of gadolinium-based contrast was 0.1 mL/kg of body weight (0.1 mmol/kg) of gadobutrol (Gadavist; Bayer Schering Pharma, Berlin, Germany).

Imaging Interpretation
Two staff neuroradiologists (A.M.M., B.K., each with >10 years of imaging experience) and 1 neuroradiology fellow (R.S.G., with
2 years of dedicated neuroradiology experience) independently graded the degree of LMCE as follows: grade 0, minimal thin vascular structures barely visible within the sulci; grade 1, thin vascular structures extending into the depths of the sulci; grade 2, smooth and slightly thickened LMCE; and grade 3, almost nodular, diffusely thickened LMCE or apparent involvement of adjacent parenchyma. The time between the commencement of the administration of intravenous contrast and the start of the postcontrast T1WI sequence was also recorded and was termed “time to imaging” (TTI).

**Statistical Analysis**

The interobserver variability was calculated regarding LMCE grades using the Cohen κ. The LMCE grade was correlated with the propofol dosage, duration of sedation, patient age, weight, and TTI using the Spearman correlation. A Mann-Whitney U test was used to compare the grades of LMCE within the group (n = 6) who underwent both GE TIWI and SE TIWI. The significance threshold was set to P < .05.

**RESULTS**

Of 152 pediatric patients (1–5 years of age) sedated by propofol for 3T MR imaging, 109 were excluded due to the lack of postcontrast T1WI (n = 96), the MR imaging being at 1.5T (n = 3), moderate-severe brain injury or congenital abnormalities, or several other factors, as listed under “Excluded Patients” within the organization chart of Fig 1. A total of 43 patients were ultimately included for MRI review; of these, 37 underwent postcontrast imaging with either solely gradient-echo T1WI (n = 20/43) or spin-echo T1WI (n = 17/43); notably, 6 patients underwent both sequences (n = 6/43). Table 1 lists the mean patient age, weight, propofol dosage, sedation duration, and TTI for both sequences. While the postcontrast TTI range was similar between sequences, it was slightly greater on SE TIWI (mean, 12.6 versus 11.0 minutes), being significantly different (P = .01).

As shown in Table 1, the range of LMCE grades of the reviewers was greater on SE TIWI (1.9–2.1) versus GE TIWI (1.2–1.4) and was significantly different (P < .0001). Interobserver κ between reviewers was strong for both GE TIWI (κ = 0.567–0.698, P < .0001) and SE TIWI (κ = 0.609–0.693, P < .0001). No patients had grade 0 LMCE on SE TIWI. Examples of the LMCE grades are provided in Figs 2–5.

When we attempted to correlate various factors with the LMCE grade, there were significant, inverse, moderate correlations between patient weight and LMCE grade, as well as age and LMCE grade (each, P < .05; Table 2). Neither the propofol dose nor the sedation duration significantly correlated with the LMCE grade. The TTI did not correlate significantly with the grade of LMCE on GE TIWI, while on SE TIWI, there was a significant, moderate correlation between the LMCE grade and TTI with only 1 of the 3 observers (a staff neuroradiologist), but not the other 2 (Table 2).

**DISCUSSION**

Because MR imaging is noninvasive and does not use ionizing radiation, it is often a technique of choice for pediatric patients requiring neuroimaging. However, its potentially long imaging
time often requires sedation in pediatric patients younger than 8 years of age. Thus, propofol is a lipid emulsion agent that is commonly the preferred anesthetic for children younger than 1 year of age who require intravenous sedation, due to its rapid onset, short duration, and infrequent side effects. Because the presence of truly abnormal LMCE would be of concern in children, this study set out to determine whether pseudo-LMCE is a sequence-dependent (SE TIWI versus GE TIWI), TTI-dependent (time to post-contrast T1WI), propofol dosage-dependent phenomenon, or whether it is related to demographics such as age and weight. Ultimately, it was found that overall, the degree of apparent LMCE is significantly greater on SE TIWI compared with GE TIWI and that the only factors that correlated (inversely) with the degree of LMCE were patient weight and age. Hence, the type of TIWI sequence and patient size may be factors to consider when a pattern of apparent LMCE would be of concern in children, this study focused solely on children between 1 and 5 years of age, future studies would be necessary to evaluate whether this phenomenon also occurs to some degree in older children and juveniles.

The mechanism of how this pattern of pseudo-LMCE occurs is not yet known, but there are several plausible explanations. The various determinants of cerebral blood flow are the patient’s age, cerebral metabolic rate for oxygen, cerebral perfusion pressure, arterial oxygen, and carbon dioxide tensions. First, children under propofol sedation breathe spontaneously, but propofol causes a decrease in the tidal volume with a maintained respiratory rate and mild reduction in the partial pressure of oxygen in the blood, as well as a mild reduction in the fraction of inspired oxygen. By this phenomenon, one likely mechanism of pseudo-LMCE may be cerebral vasodilation secondary to an increase in the partial pressure of carbon dioxide (due to smooth-muscle relaxation); this increase in the partial pressure of carbon dioxide is likely due to the lack of “breathing off” CO₂. Another factor could be that the leptomeninges may be more reactive or sensitive (in a sense “immature”) in children compared with adults, an effect perhaps amplified by intravenous sedation. Additionally, because propofol sedation may affect respiration, studies have shown that the end-tidal volume of CO₂ has an inverse relationship with the degree of venous contrast, which could also contribute to LMCE.

Hence, on the basis of reviewing the images within this study as well as the authors’ experience, the authors opine that pseudo-LMCE on cerebral postcontrast T1WI often represents prominent venous vasculature of the subarachnoid space in younger children, being anecdotally described previously as less common in older children and adults; because older ages were not included in this study, this should be proved by a prospective study comparing age groups. However, the finding in the current study of a significant, inverse correlation between patient weight and the grade of pseudo-LMCE suggests that smaller and younger patients have more vasoreactivity, perhaps because their vasculature is not as mature. This theory may be supported by a study by

**FIG 4.** Examples of grade 2 pseudo-LMCE, demonstrated on both GE TIWI and SE TIWI in 2 different patients. In a 3-year-old girl with weakness, grade 2 pseudo-LMCE appears as smooth and slightly thickened enhancement (arrows) throughout the depths of the sulci on axial (A) and coronal (B) GE TIWI. In a 5-year-old boy with headaches, there is mildly thickened vasculature diffusely throughout the sulci (arrows) on axial (C) and coronal (D) SE TIWI. Note that grade 2 enhancement was slightly more frequent on SE TIWI (35%–45%) than on GE TIWI (22%–35%).

**FIG 5.** Discrepancy of the LMCE grade between sequences: grade 3 pseudo-LMCE on SE TIWI versus grade 2 on GE TIWI in a 3-year-old boy with fever. A and B, Axial GE TIWI depicts irregular enhancement (arrows) throughout many of the sulci, being slightly thickened, consistent with grade 2 pseudo-LMCE. C and D, Axial SE TIWI in the same patient demonstrates thicker pseudo-LMCE (arrows), appearing nearly nodular or parenchymal in some locations. This case demonstrates how such pseudo-LMCE is typically more prominent on SE TIWI because grade 3 LMCE was much more frequent on SE TIWI (30%–35%) than on GE TIWI (8%–13%).
which noted that in propofol-sedated children, the usual age-related decreases in CBF were reversed and increases in CBF and CRV were weight-dependent.

Unfortunately, exuberant pseudo-LMCE in children may simulate serious disorders that have implications for diagnosis therapy, such as leading to an unnecessary lumbar puncture to exclude meningitis. A radiologist should use other available imaging sequences to exclude true leptomeningeal abnormalities before the patient leaves the MR imaging scanner. The authors commonly experience the scenario in which a child with an unrelated diagnosis (eg, developmental delay, autism, and so forth) is imaged during sedation with propofol, in which the presence of pseudo-LMCE is spurious and varies with the postcontrast T1WI sequence used and the findings of other tests such as a resultant lumbar puncture, serum culture, and so forth are negative. This phenomenon being more common and greater in degree on SE T1WI versus GE T1WI is thought to be related to GE T1WI having a longer TR and lower contrast-to-noise ratio than SE T1WI; these features have been confirmed by studies noting that GE T1WI has a lower lesion detectability and visibility of contrast enhancement for a similar slice thickness.13–15 While there was a small difference in slice gap between the 2 sequences in this study, the slice thickness and acquisition plane were coregistered between the 2 sequences, so this small gap is unlikely to account for the difference in the degree of LMCE.

Intravenous contrast is not required in most pediatric brain MR imaging examinations, and gadolinium-based contrast should be avoided when unnecessary due to the possibility of deposition within particular brain structures, especially with repeat administrations in children.16–20 While this study did use a macrocyclic agent (the class of agents least likely to result in brain deposition), the use of most gadolinium-based agents is off-label for most gadolinium based intravenous contrast agents in the infantile population but is considered a standard of care in various clinical scenarios.16–18 For example, particular known or suspected pathologies that may require either gadolinium-based contrast for diagnosis or follow-up or to exclude related pathology including infectious disorders (eg, abscess, empyema, or meningocencephalitis), neoplasms, syndromic disorders (eg, phakomatoses), vascular malformations, or vasculitis, to name a few. Hence, while stewardship is critical to lessen the use of gadolinium-based contrast, there will continue to be subsets of patients that necessitate such contrast in the foreseeable future, and an awareness of this appearance of pseudo-LMCE may help prevent a misdiagnosis of leptomeningeal disease in children.

This study has several limitations, including its retrospective nature and the relatively small sample size of groups that underwent both T1WI sequences. The role of supplemental oxygen during sedation was not accounted for, which may also affect cerebral hemodynamics and alter subarachnoid signal intensity on other sequences, such as previously noted on FLAIR.21 In this regard, the authors found it difficult to obtain an accurate tabulation of the exact fractionation of oxygen and the length of time administered while the patient was under sedation, although the electronic record did note that there was titration of the supplemental oxygen in some patients. Thus, it is recommended that future studies prospectively tabulate the oxygen fraction accurately. Another potential limitation is that there was a small but significant difference between the TTI of both SE T1WI (12.6 minutes) and GE T1WI (11.0 minutes), which might create a bias toward having a greater LMCE score on SE T1WI; however, because no significant association was noted between the degree of LMCE and TTI, such bias (if present) was unlikely to affect the LMCE grade between sequences. Another limitation was that several factors such as CSF protein, fraction of inspired oxygen, end-tidal CO2, and leakage of propofol across the BBB were not evaluated in this study. These factors, previously implicated on T2WI and FLAIR imaging, could be assessed with respect to T1WI in a future study.

### CONCLUSIONS

The phenomenon of apparent LMCE, termed pseudo-LMCE herein, is relatively common on postcontrast T1-weighted MR imaging of younger children sedated by intravenous propofol and should not be mistaken for disease. This effect occurs more commonly and to a greater degree on SE T1WI compared with GE T1WI and inversely correlates with age and weight. The presence of this finding may relate to the immaturity of younger children’s vasculature but needs to be studied further.
