THE DUST CONTENT OF GALAXY CLUSTERS

Doron Chelouche,1,2 Benjamin P. Koester,3 and David V. Bowen4

ABSTRACT

We report on the detection of reddening toward \( z \approx 0.2 \) galaxy clusters. This is measured by correlating the Sloan Digital Sky Survey cluster and quasar catalogs and by comparing the photometric and spectroscopic properties of quasars behind the clusters to those in the field. We find mean \( E(B-V) \) values of a few \( \times 10^{-3} \) mag for sight lines passing \( \sim \)Mpc from the clusters’ centers. The reddening curve is typical of dust but cannot be used to distinguish between different dust types. The radial dependence of the extinction is shallow near the cluster center suggesting that most of the detected dust lies at the outskirts of the clusters. Gravitational magnification of background \( z \approx 1.7 \) sources seen on Mpc (projected) scales around the clusters is found to be of order a few percent, in qualitative agreement with theoretical predictions. Contamination by different spectral properties of the lensed quasar population is unlikely but cannot be excluded.

Subject headings: dust, extinction — galaxies: clusters: general — intergalactic medium — quasars: general

1 INTRODUCTION

Zwicky (1957) suggested the presence of dust in the intracluster medium (ICM) to explain galaxy number counts behind the Coma Cluster and a search has begun to quantify its properties. Similar analyses were carried out by Karachentsev & Lipovetskii (1969), Bogart & Wagoner (1973), and Boyle et al. (1988, using quasars) and yielded \( B \)-band extinctions of order 0.2 mag. However, a more recent study by Maoz (1995) using radio-selected quasars behind rich Abell clusters yielded only upper limits on the reddening \( [E(B-V) = 0.05 \text{mag}] \) with similar limits \( [E(B-V) = 0.02 \text{mag}] \) obtained from the analysis of galaxy colors behind APM clusters (e.g., Nollenberg et al. 2003; see also Ferguson 1993). In contrast, Hu (1992) found \( E(B-V) \approx 0.2 \) mag toward cooling flow clusters (but see Annis & Jewitt 1993). Dust emission from clusters has been claimed to survive on large scales; see Dwek et al. 1990) unless constantly replenished or could survive on large scales; see Dwek et al. 1990) unless constantly replenished (e.g., Montier & Giard 2004) or shielded from the hot plasma (e.g., Voit & Donahue 1995). Presently, there are few meaningful constraints on the composition and quantity of intracluster dust, an understanding of which would have important implications for cluster evolution and metal enrichment processes, as well as for dust physics. In this Letter we provide new answers to 50 year old questions concerning dust in galaxy clusters, by harnessing the power of the Sloan Digital Sky Survey (SDSS).

2 METHOD

We use a 0.1 \(< z < 0.3 \) sample of \( \sim 10^4 \) optically selected clusters from Koester et al. (2007) with velocity dispersions \( > 400 \text{ km s}^{-1} \). The mean \( R_{200} \) (the radius within which the galaxy density is \( 200 \times \) the field density) is \( \sim 1 \text{ Mpc} \). The cluster center is defined by its brightest member whose position may deviate from the center of mass by a few \( \times 100 \) kpc. This sample was correlated with the SDSS DR5 spectroscopic quasar catalog (Schneider et al. 2007), identifying all quasars within 10 Mpc of the clusters’ centers. All data were corrected for Galactic extinction using the values of Schneider et al. (2007). In particular, the spectra were corrected using the reddening curve of Cardelli et al. (1989).

We employ a statistical approach to search for dust by comparing the photometric and spectroscopic properties of quasars at different impact parameters \( b \) from the cluster center with those of quasars in the field. The SDSS quasar selection criteria have no effect on the results and do not bias the observed colors for \( E(B-V) \sim 0.7E(g-i) < 0.1 \) mag (see Ménard et al. 2007). As clusters vary in size, we define a normalized impact parameter:

\[
\tilde{b} = bR_{200}.
\] (1)

A cluster would induce a mean color excess in background objects whose sight lines pass a distance \( b \) from its center (see Appendix A):

\[
\langle E(i-j) \rangle_b = \frac{2.5}{\ln 10} \left( \tau_a - \tau_b \right) + \langle \delta g - \delta B \rangle_b + \xi_b(\mu).
\] (2)

where \( i, j \) denote SDSS photometric bands, \( \tau \) the effective dust optical depth, and \( \delta B \) the foreground emission by the cluster. These terms result in effective reddening each having very different signatures (see Fig. 1 where median quasar/early-type cluster galaxy colors were used so that \( \left[ u, g, r, i, c_{\text{quasar/galaxy}} = [19.4, 19.2, 19.1, 19.0, 18.9]/[21.2, 19.9, 18.8, 18.3, 18.0] \right] \). The \( \xi_b(\mu) \) term arises when quasar colors are luminosity dependent.

The color excess is shown in Figure 1 as a function of $\tilde{b}$. Clearly, reddening in $g - i$ is detected with high significance. The color shifts are consistent with known reddening curves so that $\langle E(g - r) \rangle > \langle E(r - i) \rangle > \langle E(i - z) \rangle$, indicating that foreground emission by the cluster is negligible (see Fig. 1 and § 4). Our $\langle E(u - g) \rangle$ estimate is less secure given the known calibration issues associated with the $u$-band filter. We find $\langle E(g - i) \rangle$ values of a few $\times 10^{-3}$ mag. Inspection of the color-excess distributions (not shown) reveals that the results are not dominated by a few outliers and that most quasars are redder behind clusters. The qualitative agreement with known reddening curves suggests that $\xi$ is negligible.

Motivated by our photometric results we assume that the flux of background quasars is subject only to extinction and magnification so that the ratio of the observed (flux) spectrum, $F_{\text{obs}}$, to the intrinsic one, $F_{\text{int}}$, is

$$F_{\text{obs}}(\lambda)/F_{\text{int}}(\lambda) = \mu e^{-\tau(\lambda)},$$

where $\tau(\lambda)$ is given by the extinction curve. In our spectroscopic analysis we consider $1.5 < z < 2$ quasars which ensures (1) that lensing effects, hence $\xi$, are smaller (see Appendices A and B), (2) adequate S/N at each redshift bin (see Fig. 3 in Schneider et al. 2007 showing that $\sim 27\%$ of DR5 quasars are in this redshift range), and (3) adequate wavelength coverage excluding the Balmer continuum and emission lines band (which we verified contaminate the signal, especially in lower $z$ objects; Yip et al. 2004). A representative case is shown in Figure 2 which is nicely fit by a Cardelli extinction curve (other curves give similar results). Deviations from a smooth reddening curve at the location of the C iv $\lambda 1549$ line are probably a manifestation of the Baldwin (1977) effect (see Appendix B). Using $\chi^2$ statistics while avoiding emission-line regions and the Balmer and Fe ii line band gives

See, e.g., http://www.sdss.org/dr5/algorithms/fluxcal.html.
us the reddening and the extinction, allowing us to deduce the extinction-corrected flux ratio, i.e., the mean observed gravitational magnification, \( \mu_{\text{obs}} \) (see Fig. 2). We carried out the analysis for each redshift bin and averaged our results over all bins to produce Figure 3. Typical \( \langle E(g - i) \rangle \) values are larger than the photometrically deduced values on account of the latter being contaminated by the Balmer/Fe II band. The observed magnification is of order a few percent.

4. CONCLUSIONS

We deduce finite extinction for quasars behind clusters and our results are consistent with a large covering factor of dust toward these objects. The dust mass enclosed within a sphere of radius \( b \) is

\[
M_{\text{dust}} \sim 10^9 \left( \frac{b}{\text{Mpc}} \right)^2 \left( \frac{E(g - i)}{10^{-2} \text{ mag}} \right) M_\odot, \tag{4}
\]

(Here we used the Kramers-Kronig relations and a grain density of 2.5 g cm\(^{-3}\); Krügel 2003). This implies a dust-to-gas ratio for the ICM which is \( \lesssim 5\% \) of local interstellar medium (ISM; here we used an ICM mass of \( 4 \times 10^{13} M_\odot \) within the central Mpc; Morandi et al. 2007). If, as suggested by some theoretical models, galaxies eject their ISM in amounts comparable to their own mass during their formation, then our results imply that either the associated dust is in a clumpy form with a small covering factor or else it is rapidly destroyed and the metals are deposited in the ICM. Large-scale distributions of dust could arise from a nonvirialized gas component at the outskirts of clusters left from past merger events or related to halos of neighboring galaxies and small groups provided their size is of Mpc scales. Singular isothermal sphere (SIS) models, where dust follows dark matter, seem to overpredict the extinction on small scales (see Figs. 1 and 3) indicating that the centers of clusters may be relatively devoid of ISM-like dust.

Our results indicate that foreground emission is not important. This means that the contribution of foreground light that enters a (median) quasar’s point-spread function is \( \gtrsim 7 \) mag fainter in the \( g \) band (Fig. 1 and Appendix A) and requires that most sight lines pass \( > 10 \) (de Vaucouleur) half-light radii (\( \sim 15 \) kpc; see Fig. 4 in Bernardi et al. 2007) from a median cluster member. Repeating the entire analysis for quasars whose sight lines pass \( > 30 \) kpc from confirmed members yields similar results. We estimate foreground light contamination by resolved and nonresolved cluster members (using a luminosity function with a slope of \(-0.8\) extrapolated down to \( \sim 0.04L^\ast \), and including 25\% of blue galaxies; Hansen et al. 2007) to be at the percent level, and hence negligible.

The observed magnification was found to be few percent on Mpc scales. Correcting for luminosity function effects (see Appendix B) the intrinsic magnification is of order 10\%, which is in qualitative agreement with SIS model predictions for the magnification of a \( z = 1.7 \) quasar behind a rich \( z = 0.2 \) cluster being \( \mu = 1 - 0.2(b/\text{Mpc})^{-1} \) (e.g., Méndar et al. 2007). Given the uncertainties on the dark matter profile, our approximation for the SDSS selection function and the luminosity function of quasars, we find this agreement to be surprisingly good. It also implies that gray opacity (by large grains that survived for a Hubble time at the cluster center) is not required. The above agreement, the fact that the deduced reddening and magnification follow different trends at small \( b \) (Figs. 1 and 3), and the good fit to known reddening curves all suggest that our results are not significantly contaminated by luminosity-dependent intrinsic color differences in the lensed quasar population. The agreement between the photometric and spectroscopic results, which are prone to different systematics, is also reassuring.

We thank Brice Méndar and Keren Sharon for illuminating discussions, and the referee for valuable comments. This research has been supported by NASA through Chandra Postdoctoral Fellowship award PF4-50033. D. V. B. is funded through NASA Long Term Space Astrophysics Grant NNG05GE26G.

APPENDIX A

COLOR VARIATIONS IN OBJECTS BEHIND GALAXY CLUSTERS

Consider how an intervening cluster affects a background quasar’s flux \( F \) so that the measured flux

\[
F' = F \mu e^{-\tau} + F^{\delta F} \rightarrow \tilde{m}' = m_i + \frac{2.5}{\ln 10} \tau - 2.5 \log (\mu) + \delta^f, \tag{A1}
\]

where \( m (\tilde{m}) \) is the (measured) observed magnitude, \( \mu \) the gravitational magnification, \( \tau \) the (dust) optical depth through the cluster, and \( F^{\delta F} \) the contribution from a foreground source associated with the cluster. Here, \( i \) denotes the relevant SDSS filter band and \( \delta^f(R) \) the contribution from foreground cluster emission where

\[
\delta^f = \frac{F^{\delta F}}{F} \mu^{-1} e^{-\tau} = \frac{F^{\delta F}}{F}. \tag{A2}
\]
Defining the mean color of quasars at a given impact parameter $b$ as $\langle i - j \rangle_b \equiv \langle m_i(b) - m_j(b) \rangle$, then their color excess with respect to field quasars (i.e., at $b \to \infty$) is

$$\langle E(i - j) \rangle_b \equiv \langle i - j \rangle_b - \langle i - j \rangle_\infty = \frac{2.5}{\ln 10} \langle \tau_i - \tau_j \rangle_b + \langle \delta_l^e - \delta_l^f \rangle_b + \xi_b. \quad (A3)$$

The color excess by foreground emission may be recast in the form

$$\langle \delta_l^e - \delta_l^f \rangle = C(m_\star, m_i)e^{\Delta m_i}, \quad \text{where} \quad C \equiv 2.5\left[1 - \exp \left(\frac{m_l^e - m_l^f}{1.08} - (m_\star - m_l)\right)\right]$$

Here $m_l^e$ is due to foreground emission (see the inset of Fig. 1, where a model is plotted with a dashed line and a typical early-type galaxy spectrum is assumed to characterize the cluster’s spectral energy distribution as a whole; see § 2). The last term in equation (A3) is $\xi_b \equiv \langle m_i - m_j \rangle_b - \langle m_l - m_j \rangle_b$, which stands for the intrinsic color difference between quasars behind the cluster and field quasars. This effect can be considerable if (1) gravitational lensing is important and (2) quasar colors depend on their intrinsic luminosity. The origin of this effect is detailed below.

APPENDIX B

MEAN PROPERTIES IN MAGNITUDE-LIMITED SAMPLES

Consider a property $Q$ of quasars which depends on their intrinsic luminosity (or magnitude; assume for simplicity a narrow redshift range). In a magnitude-limited sample with selection function $\Theta(m - m_i)$ (here we approximate $\Theta$ to be a step function with a limiting magnitude $m_i = 19.1$; Schneider et al. 2007; see also Ménard 2005), the average of $Q$ is

$$\langle Q \rangle = \int_{-\infty}^{\infty} dm \Theta(m - m_i)Q(m)\Psi(m), \quad \Phi = \int_{-\infty}^{\infty} dm \Theta(m - m_i)\Psi(m). \quad (B1)$$

where $\Psi$ is the luminosity function. The difference between the measured $\langle Q \rangle$ when magnification operates (i.e., $m \to m + \Delta m$; $\Delta m > 0$) and when it does not is to first order

$$\delta\langle Q \rangle = C^\Phi \delta m \int_{-\infty}^{\infty} dm \Theta(m - m_i) \left(\frac{\partial Q}{\partial m} \Psi + \frac{\partial \Psi}{\partial m} \right) \neq 0 \to \delta\langle Q \rangle \approx (\alpha + \beta)\delta m, \quad (B2)$$

where in the last step we consider a specific example in which $Q(m) \propto e^{\alpha m}$ and $\Psi(m) \propto e^{\beta m}$. Clearly, the effect on mean quantities can have either sign, depending on the sign of $\alpha + \beta$. Taking, for example, $\alpha = -0.8$, which characterizes the dependence of quasar emission-line luminosity $L_i$ on the quasar luminosity (via the Baldwin relation; e.g., Dietrich et al. 2002), and $\beta = 1$ for the quasar luminosity function, we find that $\delta(L_i)/(L_i) \sim -1\%$, which is in qualitative agreement with our findings (note the feature at the C IV $\lambda 1549$ wavelength; Fig. 2). Less elegant expressions for geometric means lead to similar results in this case. Given the uncertainties on $\alpha$, $\beta$, it would not be surprising to find a different trend for other lines at other redshifts and luminosity ranges. Similar considerations apply also for the Balmer continuum and Fe ii lines band, yet the luminosity dependence is not well known. As for measuring the magnification itself, this corresponds to $\alpha = -1$ which, for $\beta = 1$, yields $\delta\langle Q \rangle = 0$ (i.e., $\mu = 1$). Clearly, this is not the case and a more realistic luminosity function to consider deviates from a power law and is of the form $\Psi(m) \approx [10^{-0.4(m_i - m_l)} + 10^{-0.4(m_l - m_i)}]^{-1}$ with $m_i = 19.1$, $\beta = 0.98$, and $\gamma = 0.15$ (e.g., Myers et al. 2003). Using that, we obtain that the observed mean magnification is related to the real one by $\mu - 1 \sim 3(\mu_{obs} - 1)$ (see also Ménard 2005).
