(Dated: October 21, 2014)

We present a unified view of finite-size scaling (FSS) in dimension \(d\) above the upper critical dimension, for both free and periodic boundary conditions. We find that the modified FSS proposed some time ago to allow for violation of hyperscaling due to a dangerous irrelevant variable, applies only to \(k = 0\) fluctuations, and so there is only a single exponent \(\eta\) describing power-law decay of correlations at criticality, in contrast to recent claims. With free boundary conditions the finite-size “shift” is greater than the rounding. Nonetheless, using \(T - T_L\), where \(T_L\) is the finite-size pseudocritical temperature, rather than \(T - T_c\), as the scaling variable, the data does collapse on to a scaling form which includes the behavior both at \(T_L\), where the susceptibility \(\chi\) diverges like \(L^{d/2}\) and at the bulk \(T_c\) where it diverges like \(L^2\). These claims are supported by large-scale simulations on the 5-dimensional Ising model.

I. INTRODUCTION

The method of finite size scaling (FSS)\textsuperscript{[1,2]} has been success fully applied to the analysis of the results of many numerical simulations. The main ingredient is the assumption that finite size corrections only involve the ratio of the system size \(L\) to the bulk (i.e. infinite system size) correlation length \(\xi\). The latter diverges as \(T\) approaches the transition temperature \(T_c\) like \(\xi \propto (T - T_c)^{-\nu}\) where \(\nu\) is the correlation length exponent.

While this assumption is undoubtedly correct in dimensions below the upper critical dimension \(d_u\), equal to four for most systems, the situation is, surprisingly, more complicated for \(d > d_u\), even though the critical exponents are given by their mean field values in this region. The reason is that a “dangerous irrelevant” variable causes scaling functions to have additional singularities. While the nature of FSS above the upper critical dimension has been clarified for \(k = 0\) fluctuations in systems with periodic boundary conditions, the situation in models with free boundary conditions, and for \(k \neq 0\) fluctuations for both boundary conditions, seems confused. The purpose of the work presented here is to clarify these questions and present a simple, unified, picture of FSS above the upper critical dimension.

According to standard FSS, valid for \(d < d_u\), a susceptibility \(\chi\) which diverges in the bulk like \((T - T_c)^{-\gamma}\) for \(T \to T_c\), has a FSS form

\[
\chi(L, T) = L^{\gamma y_T} \overline{\chi}(L^{\nu y_T} (T - T_c)) , \tag{1}
\]

where \(y_T\) is the thermal exponent in the renormalization group sense and is related to the correlation length exponent by

\[
y_T = \frac{1}{\nu} . \tag{2}
\]

The argument of the scaling function \(\overline{\chi}\) is proportional to \((L/\xi)^{1/\nu}\) so Eq. (1) implements the basic FSS assumption, stated above, that finite-size effects depend on the ratio \(L/\xi\). Above \(T_c\) and for large \(L\), finite-size effects disappear so we must recover the bulk result, which requires \(\overline{\chi}(x) \propto x^{-\gamma}\) for \(x \to \infty\).

Finite-size scaling is particularly simple for dimensionless (more generally scale-invariant) quantities for which the exponent \(\gamma\) above is zero. An example is the dimensionless ratio of the moments of the order parameter proposed by Binder\textsuperscript{[3]}. The Binder ratio, \(g\), defined in Eq. (17) below, has the standard FSS form

\[
g(L, T) = \overline{\chi}(L^{\nu y_T} (T - T_c)) . \tag{3}
\]

One sees that the data is independent of size at \(T_c\) so data for different sizes intersect there, which provides a very convenient way of locating \(T_c\). Furthermore, the scaling functions \(\overline{\chi}(x)\) and \(\overline{\gamma}(x)\) are predicted to be universal (apart from a non-universal metric factor multiplying the argument \(x\), and a non-universal factor multiplying the prefactor \(L^{\nu y_T}\) in Eq. (1)), so the value of \(g\) at \(T_c\) is predicted to be universal.

The purpose of the present work is to discuss how Eqs. (1) and (3) are modified for \(d > d_u = 4\). First of all we note that, in this region, we have mean-field exponents whose values are \(\gamma = 1, y_T = 1/\nu = 2\) so naively we would have

\[
\chi(L, T) = L^{2} \overline{\chi}(L^{2} (T - T_c)) , \tag{4a}
\]

\[
g(L, T) = \overline{\gamma}(L^{2} (T - T_c)) . \tag{4b}
\]

As discussed above, the power 2 in these equations is the value of the thermal exponent \(y_T(= 1/\nu)\) in the mean-field region. For periodic boundary conditions and, implicitly, for \(k = 0\) fluctuations, Binder et al.\textsuperscript{[4]} showed that one should not use the thermal exponent \(y_T\) but rather modify Eq. (4a) to

\[
\chi(L, T) = L^{\nu y_T^*} \overline{\chi}(L^{\nu y_T^*} (T - T_c)) , \tag{5a}
\]

\[
g(L, T) = \overline{\gamma}(L^{\nu y_T^*} (T - T_c)) \quad \text{(periodic, \(k=0\)}, \tag{5b}
\]

where

\[
y_T^* = d/2 . \tag{6}
\]
Since $d > 4$, we have $y_T^2 > y_T$ ($= 2$).

The universal value of $\mathcal{F}$ at $T_c$ was computed by Brézin and Zinn-Justin \cite{Brezin1975}, who showed it to be simply that obtained by including only the $k = 0$ mode (with $T_c$ adjusted to the correct value). An extensive set of works, see for example, \cite{Brezin1975, ZinnJustin1976, ZinnJustin1976b} and references therein, have shown the validity of Eq. (5), though it required large system sizes, good statistics, and an appreciation that corrections to FSS (which occur if the sizes are not big enough) are quite large and slowly decaying, to confirm the predicted, universal value of the Binder ratio at $T_c$.

Equation (5) is for periodic boundary conditions, so it is interesting to ask what happens for other boundary conditions such as free. Equation (5) is actually rather surprising since it predicts that finite-size corrections appear not when $\xi \sim L$, so $|T - T_c| \sim 1/L^2$, as one would expect, but only when $\xi \sim L^{d/4}$, a larger scale, so $|T - T_c| \sim 1/L^{d/2}$, closer to $T_c$ than expected. However, as noted by Jones and Young \cite{JonesYoung1978}, surely something must happen when $\xi \sim L$ with free boundary conditions, but what? In fact, in an under-appreciated paper, Rudnick et al. \cite{Rudnick1979}, had previously argued analytically that a temperature shift of order $1/L^2$ has to be included with free boundary conditions, in addition to a rounding of order $1/L^{d/2}$.

Even in the early days of FSS \cite{Brezin1975, ZinnJustin1976}, the possibility that a “shift” exponent could be different from the “rounding” exponent was allowed for. To explain what this means, note that the exponents $2$ in Eq. (4) and $d/2$ in Eq. (5) are “rounding” exponents since they control the range of temperature over which a singularity is rounded out ($L^{-2}$ and $L^{-d/2}$ respectively). To define the “shift” exponent we first define, for each size, a “finite-size pseudocritical temperature” $T_L$ by, for example, the location of the peak in some susceptibility, or the temperature where the Binder ratio has a specified value. The difference $T_c - T_L$ goes to zero for $L \to \infty$ like

$$T_c - T_L = \frac{A}{L^\lambda},$$

which is the desired definition of the shift exponent $\lambda$. The precise value of $T_L$ depends on which criterion is used to define it, but the exponent $\lambda$ is expected to be independent of the definition. Whether or not the amplitude $A$ depends on the quantity used to define the shift will be discussed in Sec. V.

Since the argument of the scaling function involves the difference between $T$ and the “finite-size pseudocritical temperature” $T_L$ and $y_T^2 = d/2$, see Eq. (5). The criterion that the shift is given by the condition $\xi \sim L$ yields $\lambda = 2$, as proposed by Rudnick et al. \cite{Rudnick1979} and confirmed in simulations by Berche et al. \cite{Berche1983}. As with Eq. (14), we must have $\chi(x) \propto x^{-1}$ for $x \to \infty$ in order to recover the bulk behavior above $T_c$. If we set $T = T_c$ then $L^{d/2}(T - T_L) = AL^{d/2-2}$ which is large so we can use this limiting behavior to get

$$\chi(L, T_c) \propto L^2 \quad \text{(free, k=0)},$$

a result which has been shown rigorously \cite{Brezin1975}. Hence, in contrast to Berche et al. \cite{Berche1983}, we propose that the region at the bulk $T_c$ is part of the scaling function. Similarly, for the Binder ratio, $g(x) \propto 1/x^2$ for $x \to \infty$, which gives

$$g(L, T_c) \propto \frac{1}{L^{d-2}} \quad \text{(free, k=0)}.$$  

With periodic boundary conditions, the intersection of the data for $g$ provides a convenient estimate of $T_c$, but, as Eq. (16) shows, this method cannot be used for free boundary conditions because $g$ vanishes at $T_c$ for $L \to \infty$. In fact, we shall see from the numerical data in Sec. V that there are no intersections at all. However, we will not be able to verify the precise form in Eq. (16) because the values for $g$ at $T_c$ are so small that the signal is lost in the noise.

So far we have discussed only $k = 0$ fluctuations. However, it is also necessary to discuss fluctuations at $k \neq 0$, since we need these to determine the spatial decay of the correlation functions. Of particular importance is the decay of the correlations at $T_c$, which fall off with distance like $1/r^{d-2+\eta}$, where the mean field value of the exponent $\eta$ is zero. In the mean field regime, the fluctuations of the $k \neq 0$ modes are Gaussian so the Binder ratio is always zero. For the wave-vector dependent susceptibility we shall argue that standard FSS, Eq. (5), holds for both boundary conditions, i.e.

$$\chi(k, L, T) = L^2 \tilde{X}(L^2 (T - T_c), kL), \quad \text{(both b.c.'s, k ≠ 0),}$$

where we have put the explicit $k$ dependence in a natural way as a second argument of the scaling function. For free boundary conditions, the Fourier modes are not plane waves, see Sec. V and, by $k \neq 0$, we really mean modes that are orthogonal to the uniform magnetization and so do not develop a non-zero expectation value below $T_c$.

If we fix $T = T_c$ in Eq. (11) and consider $kL \gg 1$ then the size dependence must drop out so $\tilde{X}(0, y) \propto y^{-2}$ and hence

$$\chi(k, L, T_c) \propto k^{-2} \quad \text{(kL \gg 1)}.$$  

Consequently, in real space, correlations fall off as $r^{-(d-2)}$, i.e. $\eta = 0$. It follows that non-standard FSS only affects the $k = 0$ mode and just gives a larger baseline, $\sim 1/L^{d/2}$ rather than $1/L^{d-2}$, above which the power law decay sits. We therefore do not see the need for the second $\eta$-like exponent proposed in Ref. 13.

While Eq. (11) does not seem to have been stated in the literature before, to our knowledge, it is actually quite
natural. The dangerous irrelevant variable, which is the quartic coupling in the Ginzburg Landau Wilson effective Hamiltonian, is needed to control the expectation value of the \( \langle k = 0 \rangle \) order parameter, which leads to non-standard FSS for \( k = 0 \) fluctuations. However, \( k \neq 0 \) fluctuations (more precisely, fluctuations which do not acquire a non-zero expectation value) are not affected by the dangerous irrelevant variable, and consequently have standard FSS.

The plan of this paper is as follows. In Sec. II we define the model to be simulated and the quantities we calculate. To incorporate corrections to FSS we use the quotient method which is described in Sec. III. The numerical results for periodic boundary conditions are presented in Sec. IV while those for free boundary conditions are in Sec. V. We briefly summarize our conclusions in Sec. VI.

\section{Model}
We consider an Ising model in \( d = 5 \) dimensions with Hamiltonian
\[
H = - \sum_{(i,j)} J_{ij} S_i S_j ,
\]
where \( J_{ij} = 1 \) if \( i \) and \( j \) are nearest neighbors and zero otherwise, and the spins \( S_i \) take values \( \pm 1 \). The number of spins is \( N = L^d \) and we perform simulations with periodic and free boundary conditions. Previous simulations have determined the transition temperature very precisely, finding \( T_c = 8.77846(3) \).

We simulate this model very efficiently using the Wolff \cite{17} cluster algorithm, with which we can study sizes up to \( L = 36 \) (which has around 60 million spins).

We calculate various moments of the uniform magnetization per spin
\[
m = \frac{1}{L^d} \sum_{i=1}^{N} S_i ,
\]
as well as the uniform susceptibility \cite{18}
\[
\chi = L^d \langle m^2 \rangle ,
\]
and the Binder ratio
\[
g = \frac{1}{2} \left( 3 - \frac{\langle m^4 \rangle}{\langle m^2 \rangle^2} \right) .
\]

In addition we compute the Fourier transformed susceptibilities
\[
\chi(k) = L^d \langle |m(k)|^2 \rangle ,
\]
in which the Fourier transformed magnetization, \( m(k) \), is defined differently for periodic and free boundary conditions as follows.

For periodic boundary conditions the Fourier modes are plane waves so we have
\[
m(k) = \frac{1}{N} \sum_i e^{i k \cdot r_i} S_i , \quad \text{(periodic)},
\]
where
\[
k_\alpha = 2\pi n_\alpha / L , \quad \text{(periodic)},
\]
with \( n_\alpha = 0, 1, \cdots, L - 1 \) and \( \alpha \) denotes a Cartesian coordinate.

For free boundary conditions, the Fourier modes are sine waves,
\[
m(k) = \frac{1}{N} \sum_i \left[ \prod_{\alpha=1}^{d} \sin (k_\alpha r_{i,\alpha}) \right] S_i , \quad \text{(free)},
\]
where
\[
k_\alpha = \pi n_\alpha / (L + 1) , \quad \text{(free)},
\]
with \( n_\alpha = 1, 2, \cdots, L \) and the components of the lattice position, \( r_{i,\alpha} \), also run over values \( 1, 2, \cdots, L \). There is zero contribution to the sum in Eq. (21) if we set \( r_{i,\alpha} = 0 \) or \( L + 1 \), so Eqs. (21) and (22) correctly incorporate free boundary conditions.

Note that \( k = 0 \) is not an allowed wavevector with free boundary conditions so the uniform magnetization in Eq. (13) does not correspond to a single Fourier mode. Note, too, that wavevectors with all \( n_\alpha \) odd, have a projection on to the uniform magnetization and so will acquire a non-zero expectation value below \( T_c \) in the thermodynamic limit. They will therefore be subject to the non-standard FSS in Eq. (9). However, if any of the \( n_\alpha \) are even, there is no projection onto the uniform magnetization, so they will not acquire an expectation value below \( T_c \) and will therefore be subject to the standard FSS in Eq. (11).

\section{The Quotient Method}
The discussion in Sec. II assumed that the sizes are sufficiently large and \( T \) sufficiently close to \( T_c \) that the given FSS formulae fit the data to high accuracy. For free boundary conditions, however, corrections to FSS are quite large and we need to include them in the analysis. In this section we describe the method we used to include the leading correction to FSS.

A convenient way to extract the leading scaling behavior from the data, in the presence of corrections, is the quotient method \cite{19}, which is a more modern version of Nightingale’s \cite{20} phenomenological scaling. As an example, consider the deviation of the pseudocritical temperature \( T_L \) from \( T_c \) for which the FSS expression is given in Eq. (7). Including the leading correction to scaling, which involves a universal exponent \( \omega \), one has
\[
\Delta T(L) \equiv T_c - T_L = \frac{A}{L^\lambda} \left( 1 + \frac{B}{L^\omega} \right) .
\]
We determine the quotient $Q[\Delta T]$ by taking the log of the ratio of the result for sizes $L$ and $sL$, where $s$ is a simple rational fraction like 2 or 3/2, and divide by $\ln s$, i.e.,

$$Q_{s,L}[\Delta T] = \frac{1}{\ln s} \ln \left( \frac{\Delta T(sL)}{\Delta T(L)} \right).$$

According to Eq. (23) we have, for large $L$,

$$Q_{s,L}[\Delta T] = -\lambda + C_s \frac{L}{s^\omega},$$

where

$$C_s = \frac{s^{-\omega} - 1}{\ln s} B.$$

If the data is of sufficient quality, we can fit all the unknown parameters. In Eq. (24) these would be $\lambda$, $\omega$ and $C_s$. In most cases, however, we will need to assume the predicted value for the correction exponent $\omega$, see below, and just fit to the other parameters.

According to the renormalization group, for $d > d_u = 4$, the leading irrelevant variable has scaling dimension

$$\omega = d - 4.$$  

However, for $k = 0$ fluctuations and periodic boundary conditions, it was shown in Ref. 23 that there is an additional, and larger, correction for finite-size effects, with an exponent given by

$$\omega' = \frac{d - 4}{2}.$$  

An intuitive way to see this is to note that the “naive” variation of $\chi$ with $L$ at the critical point, $\chi \propto L^2$ see Eq. (21), although not the dominant contribution (which is $L^{4/3}$, as shown in Eq. (22)), is nonetheless still present as a correction. This correction is down by a factor of $L^{2-d/2}$ ($= L^{-\omega'}$) relative to the dominant term. We shall therefore use $\omega'$ rather than $\omega$ in considering corrections to scaling for susceptibilities which scale with $L$ to the power $d/2$ rather than 2.

For some of our data we will also need subleading corrections to FSS for which there are several contributions. One of these is the square of the leading contribution. To avoid having too many fit parameters, this is the form we shall assume, i.e. when we include subleading corrections to scaling we will do a parabolic fit in $1/L^\omega$ (or $1/L^{\omega'}$ as the case may be).

A subtlety arises in doing fits to data for quotients, for example to determine the parameters $\lambda$, $\omega$ and $C_s$ in Eq. (24). The reason is that the same set of simulational data is incorporated into the pairs (8, 16) and (16, 32). Furthermore, we will do combined fits incorporating data for two different values of $s$ ($s = 2$ and 3/2), using the same exponents (since they are universal), but with different amplitudes (because they are not universal). This has the advantage of increasing the number of data points in the fit by more than the number of parameters. Again the same set of simulational data is used to determine different data points in the fit. Hence the different quotient values being fitted are not statistically independent. The best estimate of the fitting parameters should include these correlations [19, 22, 23]. In other words, if a data point is $(x_i, y_i)$, and the fitting function is $u(x)$, which depends on certain fitting parameters, those parameters should be determined by minimizing

$$\chi^2 = \sum_{i,j} [y_i - u(x_i)] (C^{-1})_{ij} [y_j - u(x_j)],$$

where

$$C_{ij} = \langle y_i y_j \rangle - \langle y_i \rangle \langle y_j \rangle.$$
is the covariance matrix of the data. We determine the elements of the covariance matrix by a bootstrap analysis \cite{24,25}. If there are substantial correlations in many elements, the covariance matrix can become singular, and where this happened we projected on to the eigenvectors of the covariance matrix whose eigenvalues are not (close to) zero, ignoring eigenvectors corresponding to zero eigenvalues. The effective number of independent data points is then the rank of the covariance matrix (the number of non-zero eigenvalues).

IV. RESULTS: PERIODIC BOUNDARY CONDITIONS

A. \(k = 0\) fluctuations

We shall be brief here, since there is no dispute that the FSS scaling in Eq. (13) is correct, but will show some results for completeness.

The left hand panel of Fig. 1 presents an overview of our data for the Binder ratio \(g\), showing intersections at, or close to, the transition temperature \(T_c\) given in Eq. (14). The expanded view in the middle panel shows that the intersections for different pairs of sizes do not occur at exactly the same, indicating corrections to scaling. In fact, the data for smaller sizes have an approximate intersection at a value larger than the exact, universal value of \(g_c\)

\[
g_c = \frac{1}{2} \left( 3 - \frac{\Gamma^4(\frac{1}{4})}{8\pi^2} \right) = 0.40578. \tag{31}\]

However, for larger sizes the intersections occur at smaller values of \(g\). The right hand panel of Fig. 1 shows an additional set of data taken at precisely \(T = T_c\), plotted against \(L^{-\omega'}\) with the correction exponent given by \(\omega' = 1/2\), see the discussion in Sec. III. The data decreases to a value consistent with Eq. (31) for \(L \to \infty\). As noted by other authors, the effect of a fairly slow correction to scaling exponent, \(\omega = 1/2\), combined, evidently, with a fairly large correction amplitude, has made it very difficult to obtain the known exact result for \(g_c\) from numerics. This should serve as a cautionary tale when applying FSS to other problems where the exact answer is not known.

B. \(k \neq 0\) fluctuations

The data for \(\chi(k)\) for \(kL/(2\pi) = (1, 0, 0, 0, 0)\) is shown in Fig. 2. Note that the Fourier components at non-zero wavevector do not develop order below \(T_c\), and so what we define as \(\chi(k)\) really is the susceptibility below \(T_c\) as well as above it (unlike the \(k = 0\) susceptibility \cite{18}), and consequently the data has a peak, whereas the uniform “susceptibility” plotted in Fig. 9 below (for free boundary conditions), continues to increase below \(T_c\).

A scaling plot of the data is shown in Fig. 3 according to the standard FSS in Eq. (11). Apart from the smallest size, \(L = 8\), near \(T_c\) the data scales very well. Going further away from \(T_c\) on the low-\(T\) side, we see bigger corrections. However, this is unsurprising since FSS is only supposed to work for \(T\) close to \(T_c\).

If go to larger \(k\)-values we get a similar picture but with bigger corrections to scaling, as shown in Fig. 4 for \(kL/(2\pi) = (1, 1, 0, 0, 0)\). It is expected that corrections to scaling become relatively bigger for larger \(k\) because the signal is less divergent in this case and so is more easily affected by corrections.

Figure 5 shows the behavior of \(\chi(k)/L^2\) at \(T_c\) showing that it is a function of the product \(kL\) as expected, see Eq. (11). The dashed line has slope \(-2\) indicating that the expected \(k^{-2}\) behavior in Eq. (12) sets in even for small values of \(kL\).

V. RESULTS: FREE BOUNDARY CONDITIONS

Since corrections to scaling are larger for free boundary conditions than for periodic boundary conditions, in this section we shall make extensive use of the quotient method described in Sec. III to incorporate the leading correction.

A. \(k = 0\) fluctuations

An overview of our results for the Binder ratio is shown in Fig. 6. We do not find any intersections and the data...
FIG. 3: (Color online) A scaling plot of the susceptibility of the data in Fig. 2. The inset shows an enlarged view near \( T_c \). The horizontal axis is \( L^2(T - T_c) \) for both plots.

FIG. 4: (Color online) A scaling plot of the susceptibility \( \chi(k) \) for \( kL/(2\pi) = (1, 0, 0, 0) \), which we abbreviate to \( \chi_{110} \), for periodic boundary conditions.

FIG. 5: (Color online) The values of \( \chi(k)/L^2 \) at \( T_c \) for periodic boundary conditions. The points for different sizes and a single \( k \) are displaced slightly horizontally so they can be distinguished. Data is shown for three different values of the \( x \)-axis: 1, \( \sqrt{2} \) and 2. There are actually two different wavevectors for \( kL/(2\pi) = 2 \), namely those with \( kL/(2\pi) = (2, 0, 0, 0, 0) \) and \( (1, 1, 1, 0, 0) \). These two agree well except for the smaller sizes, showing that the fluctuations are isotropic at long wavelength. The dashed line has slope \(-2\) indicating that the expected \( k^{-2} \) behavior in Eq. (12) sets in even for small values of \( kL \).

FIG. 6: (Color online) An overview of our results for the Binder ratio \( g \) for free boundary conditions. Note that there is no sign of any intersections and there is a large shift to lower temperatures for the smaller sizes.

is shifted considerably to lower temperatures for smaller sizes.

In order to determine the shift exponent we define the pseudocritical temperature \( T_L \) to be where \( g \) takes the
value $1/2$, halfway between its limiting values of 0 and 1. We subtract $T_c$ given in Eq. (24) and determine the resulting quotients for $\Delta T(L) = T_c - T_L$, according to Eq. (25). These quotients are then fitted according to Eq. (26), as shown in Fig. 7. The quality of the data is very good, the signal to noise is high, and we are able to fit all three parameters $\lambda$, $\omega$ and the amplitude $C$. The results for the exponents are

$$\lambda = 2.004(10), \quad \omega = 0.98(6). \quad (32)$$

This value for the shift exponent is in precise agreement with the value $\lambda = 2$ proposed analytically in Ref. 13.

There is also excellent agreement between our value of the correction to scaling exponent $\omega$ and the renormalization group value of 1.

We estimate the rounding by the range in temperature $\delta T(L)$ in which $g$ varies between 0.25 and 0.75, i.e.

$$\delta T(L) = T(g = 0.25) - T(g = 0.75). \quad (33)$$

Constructing the quotients and fitting to

$$Q_{s,L}[\delta T] = -y^s_T + A_s/L^\omega \quad (34)$$

we find that the data is insufficient to determine the three parameters, but if we assume the RG value for the correction exponent, $\omega = 1$, then we get a good fit which extrapolates to

$$y^s_T = 2.50(3), \quad (35)$$

see Fig. 8, in precise agreement with the prediction $d/2$, see Eq. (36). Thus we have established the values of the shift and rounding exponents in Eq. (36).

What about the scaling of $\chi$ in Eq. (8b)? The data for $\chi$ is shown in Fig. 9. We evaluated this at $T_L$, and did a quotient analysis which is shown in Fig. 10. The data is insufficient to determine the correction to scaling exponent, so we fixed it to the expected value $\omega' = 1/2$. The amplitude of the correction term is large, but the data extrapolates to a value 2.56(4), very close to the value of $y^f_T = 5/2$ expected from to Eq. (36).

We can also evaluate $\chi$ at the bulk $T_c$. As shown in Eq. (9), this is proportional to $L^2$, not $L^{d/2}$, and so, as discussed in Sec. 11 we expect that the correction to

\begin{align*}
\end{align*}
FIG. 10: (Color online) Quotients for value of $\chi$ at $T_L$ for free boundary conditions plotted against $1/L^{\omega'}$ where the correction to scaling exponent $\omega'$ is fixed to the value 1/2. According to Eq. $\text{(8a)}$, the quotients should extrapolate to a value of $y_T = (3/2)$ for $L \rightarrow \infty$. The linear fit omits the right-hand point for each of the data sets, and the three fitting parameters are the value of $y_T$ and two amplitudes of the correction, one for each value of $s$. The quality of the fit is good, $Q = 0.30$.

FIG. 11: (Color online) A quadratic fit for the quotients for value of $\chi$ at the bulk $T_c$ for free boundary conditions against $1/L^\omega$ where the correction to scaling exponent $\omega$ is fixed to the value 1. According to Eq. $\text{(9)}$, the quotients should extrapolate to the value of $y_T = (2)$. There are five fitting parameters: $y_T$ and the amplitudes of the linear and quadratic corrections for each $s$ value. The quality of the fit is good, $Q = 0.43$.

A quadratic fit, with the result $y_T = 2.56 \pm 0.04$ and $\omega' = 1/2$.

Corrections to scaling are quite large, which is not surprising since the values of $\chi$ at $T_c$ are quite small, and so are more influenced by several corrections to scaling than the data at $T_L$ which $\chi$ is bigger. We also tried a linear fit omitting the smallest size for each value of $s$ finding 1.89(2) which is seen to lie on the scaling function (within some small corrections.)

We have defined the pseudocritical temperatures $T_L$, and the resulting shift exponent $\lambda$, from Eq. $\text{(7)}$ by the temperature where the Binder ratio takes the value 1/2. Suppose we took a different criterion for $T_L$, such as the temperature where the Binder ratio has some other value, or where there is a peak in some $k \neq 0$ susceptibility such as that shown in Fig. $\text{[13]}$. We note that the finite-size width varies as $1/L^{\omega/2}$ so temperatures where the Binder
ratio has a value between 0 and 1 would lie in this range, and so would only give a sub-leading contribution to the shift, the coefficient of $1/L^2$ remaining the same. We expect that the same shift amplitude would be obtained no matter what quantity is used to define the shift for the following reason. Suppose we have a shift amplitude $A$ and pseudocritical temperatures $T_L$ determined from where the Binder ratio is 1/2 and a different amplitude $A'$, and correspondingly different temperatures $T'_L$, determined by some other criteria. Then the Binder ratio has scaling form in Eq. (8), but if we try to define it in terms of the alternative shift temperatures $T'_L$ we have

$$g(L, T) = \overline{\chi}(L^{d/2}(T - T_L))$$

$$= \overline{\chi}(L^{d/2}(T - T'_L) + (A' - A)L^{d/2} - 2). \quad (37)$$

Hence, if different quantities give different shift amplitudes, the argument of the scaling function would be shifted by an infinite amount (for $L \to \infty$) if we use the shift obtained from a different quantity. This would be a clear violation of scaling. We postulate that this does not happen and that there is a unique shift amplitude for a given system.

Note, however, that we cannot rule out subleading corrections to the shift of order $1/L^{d/2}$. As a result, the value of $g$ at $T_L$ according to Eq. (8) will depend on the precise definition of $T_L$ and therefore not be universal, unlike the situation with periodic boundary conditions, see Eq. (8). Hence one can view the replacement of Eqs. (8) by Eqs. (9) as a violation of standard finite-size scaling [13]. However, since the the behavior of $\chi$, for example, is described by a single function both at $T_c$ and $T_L$, we view Eqs. (8) as representing a modified FSS, distinct from standard FSS in that it has different shift and scaling exponents.

### B. $k \neq 0$ fluctuations

With free boundary conditions the Fourier modes are sine waves given by Eq. (22). Modes in which all the integers $n_\alpha$ are odd have a projection on the uniform magnetization and so will acquire a non-zero magnetization. These will be therefore be affected by the dangerous irrelevant variable and so have the same scaling as fluctuations of the uniform magnetization, given in Eq. (8a). We therefore take the smallest wavevector with an even $n_\alpha$, namely $n = (2, 1, 1, 1)$, since this will not acquire a non-zero magnetization so we expect it to be governed by the FSS in Eq. (11), i.e. with exponent 2 rather than $d/2$ which appears in Eq. (8a). We show the data in Fig. 13.

According to Eq. (11) the height of the peaks in Fig. 13 should scale as $L^2$ and the width should scale as $L^{-2}$. We define the width to be the difference between the two temperatures where the susceptibility is 3/4 of that at the maximum. The quotient analyses for height and width are shown in Figs. 14 and 15 respectively. For the height the (quadratic) fit gives an extrapolated value of 2.010 (24) which agrees with the expected value of $y_T = 2$. As discussed in the caption to Fig. 14 a linear fit gave a value 1.950 (2), close to but slightly different from 2. However, the quality of fit factor $Q = 0.002$[21] was unacceptably low, which is why we went to a quadratic
fit. For the data of the width in Fig. 15 the dependence on size is modest and we find an extrapolated value of $-1.97(4)$ well consistent with the expected value of $-y_T (=-2)$ for $L \to \infty$. The amplitude of the correction to scaling is seen to be quite small in this case, and the quality of linear fit is excellent: $Q = 0.67$.

Consequently we have found strong evidence to support our claim that Eq. (11) applies to free boundary conditions. Note that since this FSS scaling form uses $y_T (= 2)$ and the deviation of $T_L$ from $T_c$ is proportional to $1/L^2$, asymptotically we can use either $T_c$ or $T_L$ in Eq. (11).

VI. SUMMARY AND CONCLUSIONS

Our main conclusions have already been discussed in the introduction so we will be brief here. FSS above the upper critical dimension can be summarized by:

1. The modified FSS form with exponents $d/2$ rather than 2 only applies to $k = 0$ fluctuations. (For free boundaries, it applies to Fourier modes which have a projection onto the uniform magnetization.) For all other wavevectors, standard FSS with an exponent 2 applies. As a result there is only one exponent $\eta$ describing the power-law decay of correlations at $T_c$ in contrast to recent claims.

2. For free boundaries and at $k = 0$, the shift, with an exponent 2, is larger than the rounding, which has an exponent $d/2$. Using $T - T_L$, where $T_L$ is the finite-size, pseudocritical temperature, rather than $T - T_c$, as a scaling variable, the data has a scaling form which incorporates both the behavior at $T_L$ where $\chi \propto L^{d/2}$ and at the bulk $T_c$ where $\chi \propto L^2$.

[18] This expression differs from the standard expression for the susceptibility $\chi = \beta L^d (\langle m^2 \rangle - \langle m \rangle^2)$ in two ways. The first trivial difference is that we omit the factor of $\beta$ which is conventional in critical phenomena studies. Secondly, and not so trivially, we ignore the subtracted term, which is hard to compute reliably by Monte Carlo since one has to apply a field $h$ and take the limit $h \to 0$ after the limit $L \to \infty$. Hence the quantity we call $\chi$ is really only the susceptibility above $T_c$. It is, nonetheless, a convenient quantity to study, and has the claimed scaling behavior.
