Diquarks may play an important role in hadron spectroscopy, baryon decays and color superconductivity. We investigate the existence of diquark correlations in lattice QCD by considering systematically all the lowest energy diquark channels in a color gauge-invariant setup. We measure mass differences between the various channels and show that the positive parity scalar diquark is the lightest. Quark-quark correlations inside the diquark are clearly seen in this channel, and yield a diquark size of $O(1)$ fm.

Diquarks were originally proposed several decades ago [1] as a natural way to explain the absence of a large number of exotics otherwise predicted by QCD. Recently, it has been realized that they provide a natural explanation for an exotic baryon antidecuplet, the $\Theta^+$ [2], that can not be accommodated in the quark model. The first evidence for the $\Theta^+$ was reported by the LEPS Collaboration [3], but subsequent experiments cast doubts on its existence [4]. Independently of whether a pentaquark exists or not, diquark correlations may play an important role in the description of quark distributions and fragmentation functions and in explaining the systematics of non-leptonic weak decays of light quark hadrons [5]. In addition diquarks are the central ingredient of cold, dense matter where they condense to form a color superconductor. Despite their potential role in explaining such systematics, diquark states are excluded in quark models. We expect them to be present in QCD at high densities or not, diquark correlations may play an important role in the description of quark distributions and fragmentation functions and in explaining the systematics of non-leptonic weak decays of light quark hadrons [5]. In addition diquarks are the central ingredient of cold, dense matter where they condense to form a color superconductor. TABLE I: Summary of our simulations, including the value of \( \kappa \), which determines the bare quark mass, the pion mass, \( m_\pi \), and nucleon mass, \( M_N \), in lattice and, for the latter, in physical units and the number of gauge configurations.

| \( \kappa \) | \( a m_\pi \) | \( a M_N \) [\( M_N \) GeV] | number of cons |
|-------|-------|------------------|-------------|
| Quenched \( 16^3 \times 32 \) \( \beta = 5.8 \), \( a^{-1} = 1.47 \text{ GeV} \) | 0.1560 | 0.619(2) [1.139(8) [0.204(1)]] | 356 |
| Quenched \( 16^3 \times 32 \) \( \beta = 6.0 \), \( a^{-1} = 2.15 \text{ GeV} \) | 0.1550 | 0.579(2) [1.052(9) [1.55(1)]] | 160 |
| Quenched \( 16^3 \times 32 \) \( \beta = 6.2 \), \( a^{-1} = 2.94 \text{ GeV} \) | 0.1510 | 0.423(1) [0.783(8) [1.68(2)]] | 364 |
| Quenched \( 20^3 \times 40 \) \( \beta = 6.0 \), \( a^{-1} = 2.42 \text{ GeV} \) | 0.1575 | 0.270(3) [0.580(7) [1.40(2)]] | 185 |

The mass of our static-light-light baryon can be obtained from the large time limit of the correlator

\[
G_t(t) = \langle J_1(x, t) J_1(x, 0) \rangle,
\]

The effective mass, \( m_{\text{eff}}(t) = -\log \left[ G_1(t)/G_1(t-1) \right] \), becomes time independent for large \( t \) when the lightest state dominates (plateau region), yielding its mass. To reduce the statistical errors, we need to keep \( t \) small by isolating the ground state as fast as possible. This is accomplished by using curves with higher excitations using Wuppertal smearing \cite{12} on the source and sink with hypercubic (HYP) smeared spatial links \cite{13} for the Wuppertal smearing function \cite{14}. In addition we use HYP smearing on the temporal gauge links \( U_\lambda(x) \) that enter in the construction of the static propagator given by

\[
S_{\text{stat}}(x_2, t_2, x_1, t_1) = \delta^3(x_2 - x_1) \left( \frac{1 + \gamma_0}{2} \right) \prod_{i=t_1}^{t_2 - a} U_\lambda(x_1, t_i)
\]

for \( t_2 > t_1 \). The exponential prefactor \( \exp(-m_q(t_2 - t_1)) \) has been dropped, since this introduces a constant shift in all energies by the bare heavy quark mass \( m_q \), which cancels in the mass differences that we measure between baryons with diquarks in different channels.

We show in Fig. 1 the effective mass differences, \( \Delta m_{\text{eff}} \), between the “good” (scalar) diquark created by taking \( \Gamma = 7 \), and the other channels. As expected the mass difference is zero for the other scalar diquark with positive parity created by taking \( \Gamma = 0 \). The other positive parity channels, i.e. the “bad” (vector) diquarks, are degenerate and are clearly higher in energy than the “good” diquarks as pointed out in Ref. \cite{8}. The negative parity states, as expected, have even larger energies. Their effective masses are much noisier making it difficult to identify a clear plateau void of contamination from yet higher states. The general behavior is however similar to the positive parity diquarks: the vector channels are also degenerate and tend to have a larger mass than the scalar channel created by taking \( \Gamma = I \). To verify that the mass difference seen between the two scalar channels is significant one would need to improve the quality of the mass plateaus.

Effective color-spin Hamiltonian arguments \cite{8} predict that for heavy constituent quarks the mass difference \( \Delta m \equiv m_{\gamma_0} - m_{\gamma_5} \) between the “good” and “bad” diquarks scales like \( 1/m_q \), where \( m_{\gamma_0, \gamma_5} \) are the masses of the constituent quarks. On the other hand in the light quark regime we have \( m_2 \sim m_q \). Therefore for intermediate values of \( m_q \), where both relations hold approximately, we make the Ansatz \( \Delta m \sim 1/m_q^4 \). In the opposite limit \( m_q \to 0 \), \( \Delta m \) is expected to approach a constant value. These two behaviors can be connected by the Ansatz

\[
\Delta m = \frac{c_1}{1 + (m_q/c_2)^4},
\]

with \( c_1 \) and \( c_2 \) to be determined from the lattice data. We show in Fig. 2 results for \( \Delta m \) as a function of \( m_q^4 \) for our three \( \beta \) values. All lattice data should fall on a universal line if we are close to the continuum limit. We observe that this is indeed the case on our two finest lattices whereas for the coarsest, scaling violations are apparent. In the same figure we also show \( \Delta m \) obtained using unquenched, dynamical Wilson configurations. It nicely falls on the same curve as the fine-lattice quenched results. This corroborates that scaling has set in and that quenching effects at these quark masses are small. Therefore a quenched study of diquark properties in the quark mass range used here is a very good approximation and will be adopted in the rest of the discussion. The Ansatz given in Eq. (4) provides a good fit to the lattice data. Using the lattice data with good scaling behavior at \( \beta = 6.0 \) and 6.2, we find \( c_2 = 0.78 \pm 0.15 \text{ GeV} \) and \( c_1 = 0.138 \pm 0.01 \text{ GeV} \), which is the mass difference at the chiral limit \cite{15}. This mass splitting can be compared to the \( 
\Delta \)-nucleon mass splitting, \( \delta m_{\Delta N} \). Using our quenched data at \( \beta = 6.0 \) we find for the ratio \( \Delta m/\delta m_{\Delta N} = 0.67(7), 0.73(8) \) and 0.67(8).
at $\kappa = 0.153, 0.154$ and $0.155$ respectively. Therefore our estimate of $\Delta m$ is consistent with the predicted $\frac{2}{3}$ of the $\Delta$-nucleon mass difference given in Ref. [8].

Fig. 2: Mass difference between “good” and “bad” diquarks as a function of $m^4_\pi$ at $\beta = 5.8$ (crosses), $\beta = 6.0$ (open triangles), $\beta = 6.2$ (filled circles) and unquenched result (filled square). The dashed lines are fits to Eq. (4).

FIG. 3: $C_\Gamma(r/a = 7.35, \theta)$ versus $\cos(\theta)$ for $\beta = 6.2$ and $\kappa = 0.1520$ for the “good” diquark (asterisks) and the other diquark channels using the same notation as in Fig. 1. Correlators for the “bad” diquark have been multiplied by two and for all negative parity channels by ten.

Having determined the diquark spectrum, we now turn to the analysis of their structure by studying the density-density correlators defined in Eq. (1). The time $t$ where the density operators are inserted is shown in Fig. 1 by the arrow (at $t/a = 8$), and is within the plateau range of the effective mass. We have verified that the correlators remain, within errors, unchanged when we vary the source-sink separation or equivalently $t$. Our aim is to look for spatial correlations between the two light quarks in the various diquark channels. We take the location of the static quark as the reference coordinate from which the distances $r_u$ and $r_d$ of the two quarks of different flavors are measured. We are interested in intrinsic diquark correlations, which persist as the static quark is moved away from the diquark. We therefore consider spherical shells $|r_u| = |r_d| = r$ of increasing radius $r$. Since the system is spherically symmetric the correlator depends only on $r$ and the angle $\theta = \arccos(r_u \cdot r_d)$ [6]. In the absence of any correlation, the distribution of $C_\Gamma(r, \theta)$ will be uniform as a function of $\cos(\theta)$. Attraction will show up as an enhancement at small angles, near $\cos(\theta) = 1$. Our cubic lattice breaks rotational symmetry and distorts the uniform spherical distribution, particularly at small angle $\theta$. To remove such lattice artifacts, we normalize our distributions by a uniform lattice distribution. We show the resulting density correlators in Figs. 3 and 4 for various shell radii $r$. The physically relevant correlations are those that survive when $r$ is large. We indeed observe that the qualitative behavior of the distributions does not depend on $r$, confirming that the color field generated by the static quark does not affect the physics of diquarks once $r$ is large enough.

In Fig. 3 we show $C_\Gamma(r/a = 5.1, \theta)/C_{\gamma_5\gamma_5}(r/a = 5.1, 0)$ versus $\cos(\theta)$. For the “good” (asterisks) and “bad” (filled triangles) diquarks at the lightest pion for our three lattice spacings.
masses. The negative-parity correlators are noisier because the diquarks are heavier, so that a higher statistics analysis will be needed to fully determine the characteristics of their distributions. For this reason, we now restrict our analysis to the positive parity diquarks.

\[
\delta L = \frac{2(\sqrt{3} - 1/2\sqrt{3})}{\epsilon/2} = \sqrt{\frac{3\epsilon}{2}}
\]

FIG. 5: String formation for three quarks, where one quark has been taken to the distant left. As a function of the separation between the other two quarks, the static potential rises with an effective string tension \( \sigma_{\text{eff}} = \sigma / \sqrt{3} \).

In Fig. 4 we show the density correlators for the “good” (scalar) and “bad” (vector) diquarks for all three lattice spacings at our lightest quark mass. The left hand set shows the correlator as a function of \( \cos(\theta) \) normalized to 1 at \( \theta = 0 \) for \( r/a = 5.1 \), which corresponds to \( r = 0.69 \), 0.47 and 0.35 fm at \( \beta = 5.8, 6.0 \) and 6.2 respectively. As can be seen, irrespectively of the distance the “good” diquark shows stronger spatial correlations. Within this framework we can also extract the diquark size: At fixed \( r \) we look at the dependence of the correlator on the relative \( u - d \) separation, \( r_{ud} = 2r \sin(\theta/2) \). In the right hand of Fig. 4 we show the correlator (normalized to 1 at the origin) as a function of \( r_{ud} \) for a fixed physical shell radius \( r = 0.5 \) fm, at our lightest quark mass. An exponential dependence of \( C_\theta(r, r_{ud}) \propto \exp(-r_{ud}/r_0(r)) \) provides a gauge invariant definition of the diquark size \( r_0(r) \) for a given value of \( r \). The curves in Fig. 4 obtained from fits to an exponential dependence, describe well \( C_\theta(r, r_{ud}) \) at all \( \beta \) values. Moreover the physical size \( r_0(r) \) is the same on the two finer lattices, confirming continuum-like behaviour as for the diquark masses. We can then evaluate \( r_0 \) as a function of the shell radius \( r \). Our measurements show a mild increase of \( r_0 \) with \( r \), from \( \sim 0.9 \) fm to \( \sim 1.3 \) fm as \( r \) increases from 0.3 to 0.75 fm. For large \( r \gtrsim 0.5 \) fm, \( r_0 \) is consistent with having reached a plateau. This suggests that the static source has a small influence on the “good” diquark giving a characteristic size of about \( 1.1 \pm 0.2 \) fm. For comparison, at the same quark mass and using the same definition of size, we find for the \( \rho \) a size of 0.7 fm [3]. The large diquark size can be understood from the following qualitative argument: As the static quark is moved away from the diquark a \( q\bar{q} \) string tension develops. Considering an increase \( \epsilon \) in the separation between the quarks in the diquark as illustrated in Fig. 5 one finds that the effective \( q\bar{q} \) string tension is \( (\sqrt{3}/2) \sigma \) where \( \sigma \) is the \( q\bar{q} \) string tension. Since in the perturbative regime, the \( q\bar{q} \) attraction is also weaker than the \( q\bar{q} \) attraction, this time by a factor 1/2, the conclusion is that for all distances one expects the \( q\bar{q} \) attraction to be weaker. Thus a \( q\bar{q} \) diquark should be somewhat larger than a \( q\bar{q} \) meson, which is what we find. Size measurements for the “bad” diquark, on the other hand, show neither scaling nor convergence to a plateau value. The large values obtained, often similar to our box size, corroborate the weakness of spatial correlations in this channel.

In conclusion, we have evaluated the mass splittings and density correlators of the complete set of diquark channels created by local diquark fields. Both observables confirm the phenomenological expectation that QCD dynamics favors the formation of “good” diquarks, i.e., in the scalar positive parity channel. The characteristic size of this diquark, \( O(1) \) fm, is large but consistent with the scale \( O(200) \) MeV of the attraction. Even a “good” diquark is a large object, which may limit its relevance to hadron structure. The positive parity vector channel is higher in energy by about \( 2/3 \) the \( \Delta \)-nucleon mass splitting, and forms an even larger object. All the negative parity channels have much higher energies.
