Abstract: The diurnal temperature range (DTR) is considered a signature of observed climate change, which is defined as the difference between the maximum (T max) and minimum temperatures (T min). It is well known that the warming rate of mean temperature is larger at high elevations than at low elevations in northeast China. However, it is still uncertain whether DTR trend is greater at high elevations. This study examined the spatiotemporal variation in DTR and its relationship with elevation in northeast China based on data from 68 meteorological stations from 1961 to 2015. The results show that there was a significant declining trend (0.252 °C/decade) in DTR from 1961 to 2015 due to the fact that T min increased at a faster rate than T max. Seasonally, DTR in northeast China showed a decreasing trend with the largest decrease rate in spring (−0.3167 °C/decade) and the smallest decrease rate in summer (−0.1725 °C/decade). The results of correlation analysis show that there was a significant positive correlation between the annual DTR trend and elevation in northeast China. This is due to the fact that increasing elevation has a significant warming effect on T max. Seasonally, there were significant positive correlations between the DTR trend and elevation in all seasons. The elevation gradient of DTR trend was the greatest in winter (0.392 °C/decade/km) and the lowest in autumn (0.209 °C/decade/km). In spring, summer, and autumn, increasing elevation has a significant warming effect on T max, leading to a significant increase of the DTR trend with increasing elevation. However, in winter, increasing elevation has a significant cooling effect on T min, resulting in a significant increase of the DTR trend with increasing elevation.

Keywords: diurnal temperature range; maximum temperature; minimum temperature; northeast China; temperature trends; elevation dependency

1. Introduction

According to the Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment Report (AR5), the global climate has warmed by about 0.74 °C in the last century [1]. The intensified warming contributes to a series of extreme climate events, such as droughts, floods, and heat and cold waves [2]. Diurnal temperature range (DTR), defined as the difference between the maximum temperature (T max) and the minimum temperature (T min), is a meteorological indicator related with global and regional climate change. Furthermore, it provides more information on climate change than mean temperature due to its relationship with T max and T min and its sensitivity to radiation energy balance change [3–6]. Therefore, DTR is considered as an important indicator and is receiving much more attention in regional and global scale in recent times [7–10]. Previous studies have reported that DTR changes were not uniform globally, which was attributed to complicated interactions of local climatic and anthropogenic factors [11,12]. In most parts of world, it is reported that DTR decreased with individual rate, such as in Bangladesh [13], Australia [14], and United...
States [15]. However, an increase of DTR was reported in India [16]. Because DTR change is different indifferent regions, investigating the DTR change at regional scale is necessary for understanding the global climate change.

Northeast China is located at the highest latitude and in the coldest region in China, and it is one of the most significant warming regions in China [17,18]. Furthermore, northeast China is one of the biggest grain production bases in China, accounting for approximate 20% of China’s total grain production. Grain production strongly depends on temperature during the growing season [19,20]. Therefore, it is necessary to investigate the spatial and temporal long-term temperature change in northeast China. Many scholars have studied the variation of temperature in northeast China. Mwagona et al. [21] found that $T_{\text{min}}$ increased at a faster rate than $T_{\text{max}}$, leading to the decrease of DTR in northeast China. Shen et al. [22] obtained similar results using data from meteorological stations. Based on Earth System Model’s low-warming simulations released by the National Center for Atmosphere research, Hu et al. [23] found DTR will decrease at a rate of $-0.4 \, ^\circ\text{C}/\text{decade}$ ($-1.5 \, ^\circ\text{C}/\text{decade}$) under the 1.5 $^\circ\text{C}$ (2.0 $^\circ\text{C}$) warming scenario. According to data from meteorological stations, Sun et al. [24] found the mean, maximum, and minimum temperatures exhibited increasing trends from 1951 to 2014. Recently, most studies have focused on the horizontal distribution of temperature change. Northeast China includes Changbai Mountain, Da and Xiao Xing’anling Mountains, Songnen Plain, and Sanjiang Plain, which leads to significant differences in elevation. The complexity of topography further causes temperature change to be far from uniform [25–27]. It is reported that high-elevation regions have warmed at a faster rate than low-elevation ones in East Asia [28]. For example, Liu et al. [29] found that the $T_{\text{min}}$ trend magnitude is more prominent at high elevation than that at low elevation in the Tibetan Plateau, especially in winter and spring. Thakuri et al. [30] found that the observed positive elevation-dependent warming for $T_{\text{max}}$ until 2566 m could be related to the reduced number of rainy days in Nepal from 1976 to 2015. Dong et al. [31] investigated the relationship between temperature trend and elevation by dividing China into three subregions and found the temperature trend changed with elevation. Xu et al. [32] confirmed that the elevation dependency of warming was most significant in winter, followed by spring, summer, and winter in Hengduan Mountain. Dimri et al. [33] used three different regional climate models to assess the probable future changes in $T_{\text{max}}$ and $T_{\text{min}}$ and confirmed that the insignificant increase of the $T_{\text{max}}$ trend and the significant decrease of the $T_{\text{min}}$ trend with elevation resulted in a significant increase of the DTR trend magnitude with elevation in winter. However, few studies have studied the relationship between the temperature trend and elevation in northeast China. Thus, it is necessary to understand the impact of elevation on DTR change, which is used for understanding climate change in mountain regions.

In this study, we collected data from 68 meteorological stations in northeast China from 1961 to 2015. By analyzing the monthly observation data, we examined the spatial and temporal changes of DTR and its relationship with elevation. Finally, we analyzed the plausible mechanisms that can explain the relationships between temperature trends and elevation.

2. Method and Data

Data used in this study included monthly $T_{\text{max}}$, $T_{\text{min}}$, and sunshine duration (SD) and station elevation, provided by the National Meteorological Information Center, China Meteorological Administration (NMIC/CMA). During the study period, the same standards and instrumentation were used for all meteorological stations. According to the standard of no more than 2% missing data, 68 meteorological stations were selected to investigate the climate change in northeast China from 1961 to 2015. Figure 1 shows the distribution of the 68 meteorological stations in northeast China. The elevation of these meteorological stations varies from 3 to 1017 m (Figure 2). In the aspects of climate condition, northeast China is characterized by a cool-temperate continental monsoon climate with long winter and short warm summer [34–36]. The annual average temperature gradually increases...
from approximately $-1 \, ^\circ C$ in the northeast to $6 \, ^\circ C$ in the south. The annual precipitation in northeast China gradually increases from about 400 mm in the west to 1000 mm in the east. The precipitation in northeast China is mainly concentrated in summer [37].

The data processing was described in our previous study [22]. We used the method proposed by Wang and Gaffen [38] to assure the quality and consistency of data. To supply the missing data, linear interpolation and stepwise were used. The method used to fill the data gaps cannot affect the results in analyzing climate change. The missing data accounted for less than 0.35% of the total records. According to filled data and raw data, we calculated the means and trends, respectively. It was found that the difference between the two datasets was insignificant. In this study, gap-filled data were used because the missing data mainly concentrated in the early years.
The trend in annual and seasonal $T_{\text{max}}$, $T_{\text{min}}$, DTR, and SD were analyzed quantitatively by linear regression. The magnitude of change for $T_{\text{max}}$, $T_{\text{min}}$, DTR, and SD were determined by the tenfold slope. The altitude gradient of temperature tendency rate was also estimated by linear regression, shown by Equation (1).

$$y = k_0 + k_1 \text{ele}$$

where $y$ is warming rate; $\text{ele}$ is elevation at each station; and $k_0$ and $k_1$ are regression coefficients. The coefficient $k_1$ represents the altitude gradient. The correlation coefficient was applied to determine the relationship between elevation and the trends of climate factors (DTR, $T_{\text{max}}$, $T_{\text{min}}$, and SD). The correlation coefficient was also used to determine the relationship between the trend of SD and the trend of temperature ($DTR$, $T_{\text{max}}$, and $T_{\text{min}}$). Finally, $t$-test was used for significance test. The trend was considered to be statistically significant when $p < 0.05$.

The seasons include spring, summer, autumn, and winter in this study. Spring is from March to May, summer is from June to August. autumn is from September to November, and winter is from December to February.

3. Results
3.1. Temperature Characteristics

The analysis results of the annual temperature trend in northeast China are shown in Figure 3. Annual $T_{\text{max}}$ and $T_{\text{min}}$ in northeast China increased significantly from 1961 to 2015. Annual $T_{\text{max}}$ showed a warming trend ($0.209^\circ \text{C}/\text{decade}$), and 94% of stations reached the 95% level of significance (Table 1). Annual $T_{\text{min}}$ trend increased by $0.454^\circ \text{C}/\text{decade}$, and all stations reached 95% level of significance (Table 1). Although annual $T_{\text{max}}$ and $T_{\text{min}}$ increased significantly from 1961 to 2015, the trend of $T_{\text{min}}$ was larger than that of $T_{\text{max}}$, which led to a significant decreasing trend of DTR in northeast China. Annual DTR decreased significantly at a rate of $-0.252^\circ \text{C}/\text{decade}$, and 91% of stations reached the 95% level of significant (Table 1).

![Figure 3](image.png)

**Figure 3.** Time series of annual mean DTR, $T_{\text{max}}$, and $T_{\text{min}}$ in northeast China from 1961 to 2015. The solid lines represent the linear fit.

| Season  | DTR  | $T_{\text{max}}$ | $T_{\text{min}}$ |
|---------|------|-----------------|-----------------|
| Spring  | 55   | 19              | 68              |
| Summer  | 40   | 41              | 67              |
| Autumn  | 40   | 51              | 67              |
| Winter  | 57   | 21              | 58              |
| Annual  | 61   | 64              | 68              |

**Table 1.** Number of stations that reach the significant level ($p < 0.05$).
Considering the seasonal characteristics, DTR in northeast China decreased significantly in all seasons, exceeding 95% level of significance (Table 2). The decrease of DTR was higher in spring and winter than that in summer and autumn. T\textsubscript{min} deceased significantly, but T\textsubscript{max} showed an insignificant change during spring and winter. As a result, DTR decreased significantly at greater rates during spring and winter. T\textsubscript{max} and T\textsubscript{min} increased significantly during summer and autumn, exceeding the 95% level of significance. Warming rates of T\textsubscript{min} were greater than those of T\textsubscript{max}. Therefore, DTR decreased significantly at slower rates during summer and autumn. On the other hand, we also found that the increases of T\textsubscript{max} and T\textsubscript{min} were the greatest in winter (0.5261 and 0.2298 °C/decade).

### Table 2. Seasonal trends (°C/Decade) of T\textsubscript{max}, T\textsubscript{min}, and DTR in northeast China from 1961 to 2015.

| Season  | Tmax | Tmin  | DTR   |
|---------|------|-------|-------|
| Spring  | 0.189| 0.506**| −0.317**|
| Summer  | 0.195**| 0.368**| −0.173**|
| Autumn  | 0.224* | 0.417**| −0.193**|
| Winter  | 0.230 | 0.526**| −0.297**|

* Significant at p < 0.05, ** Significant at p < 0.01.

### 3.2. Relationship between Temperature and Elevation

Elevation is one of the factors influencing the distribution of temperature trend. Therefore, for the distribution of DTR trend, we mainly analyzed the influence of elevation on temperature trend. The correlation coefficient was used to estimate the relationship between temperature and elevation.

The results of correlation analysis are shown in Figure 4. There was a significant positive correlation between annual T\textsubscript{max} trend and elevation in northeast China (Figure 4a). This indicated that increasing elevation had a warming effect on T\textsubscript{max}. By contrast, a negative correlation between the annual T\textsubscript{min} trend and elevation was found (Figure 4b), although it was not significant. These results lead to a significant positive correlation between the DTR trend and elevation. This result confirms those of previous studies that increasing elevation is positively correlated with DTR [30,39]. When the elevation increased 1000 m, the DTR tendency rate increased by 0.293 °C/decade in northeast China.

![Figure 4. The relationship between elevation and (a) annual DTR, (b) annual T\textsubscript{max}, and (b) annual T\textsubscript{min} trends in the northeast China during 1961–2015. ** Significant at p < 0.01.](image)

To further prove the influence of elevation on temperature, we calculated the correlation coefficient between temperature trends and elevations during different seasons.
The analysis results of the relationship between seasonal trend and elevation is shown in Table 3. Similar to the results of annual analysis, there were significant positive relationships between the DTR trend and elevation in all seasons in northeast China. Significant positive correlations between the \( T_{\text{max}} \) trend and elevation were found in spring, summer, and autumn. However, the relationship between the \( T_{\text{min}} \) trend and elevation was not significant in spring, summer, and autumn. It resulted in a significant positive correlation between the DTR trend and elevation in spring, summer, and autumn. Therefore, increasing elevation had a warming effect on DTR. In winter, the results of correlation analysis show that there was a significant negative correlation between the \( T_{\text{min}} \) trend and elevation in northeast China. This indicated that increasing elevation had a cooling effect on \( T_{\text{min}} \). However, we found no significant correlation between the \( T_{\text{max}} \) trend and elevation. This also led to a significant positive correlation between the DTR trend and elevation. Therefore, increasing elevation also had a warming effect on DTR in winter. The greatest altitude gradient of the DTR trend occurred in winter. With the elevation increasing 1000 m, the DTR tendency rate increased by 0.392 \(^{\circ}\)C/decade. The lowest altitude gradient of DTR trend occurred in autumn. When the elevation increased 1000 m, the DTR tendency rate increased by 0.209 \(^{\circ}\)C/decade.

Table 3. Relationships between elevation and the \( T_{\text{max}} \), \( T_{\text{min}} \), and DTR trends in northeast China. “R” represents the correlation coefficient, while “slope” represents the altitude gradient of temperature.

|       | \( T_{\text{max}} \) | \( T_{\text{min}} \) | DTR |
|-------|---------------------|---------------------|-----|
|       | R                   | Slope \(^{\circ}\)C/decade/km | R     | Slope \(^{\circ}\)C/decade/km | R     | Slope \(^{\circ}\)C/decade/km |
| Spring| 0.551 **            | 0.205               | −0.209 | −0.142               | 0.438 ** | 0.348               |
| Summer| 0.572 **            | 0.254               | 0.042  | 0.028               | 0.389 ** | 0.226               |
| Autumn| 0.384 **            | 0.100               | −0.16  | −0.109               | 0.303 *  | 0.209               |
| Winter| 0.194               | 0.095               | −0.322 ** | −0.299               | 0.425 ** | 0.392               |

*Significant at \( p < 0.05 \), ** Significant at \( p < 0.01 \).

4. Discussion

4.1. Comparison with Previous Studies

DTR in northeast China decreased significantly at a rate of \(-0.209^{\circ}\)C/decade from 1961 to 2015. This result is lower than the result of Shen et al. [22] \((-0.273^{\circ}\)C/decade from 1962 to 2011). This is probably caused by the different study period. In this study, \( T_{\text{min}} \) increased at a faster rate than \( T_{\text{max}} \) from 1961 to 2015. The change of DTR is mainly caused by the asymmetry of the \( T_{\text{max}} \) and \( T_{\text{min}} \) trends. Some research has found that \( T_{\text{min}} \) is rising more quickly than \( T_{\text{max}} \) in China [22], which is consistent with our result. A similar pattern was also observed in Bangladesh [13]. However, different from what was observed in Nepal, the \( T_{\text{max}} \) trend was greater \((0.45^{\circ}\)C/decade\)) than the \( T_{\text{min}} \) trend \((0.09^{\circ}\)C/decade\)), leading to significant increasing trend of DTR from 1976 to 2015 \((0.34^{\circ}\)C/decade\)) [30]. Kattel et al. [40] also found that the increasing trend of \( T_{\text{max}} \) was greater than that of \( T_{\text{min}} \) on the southern of slope of the Himalayas. This is possibly due to the fact that, different from northeast China, other factors may influence the trends of temperature change.

Previous studies found that only the warming rate of \( T_{\text{min}} \) was the greatest in winter (from 1950 to 1993) [5]. However, Vose et al. [10] found that \( T_{\text{max}} \) and \( T_{\text{min}} \) in the Northern Hemisphere showed the greatest changes in winter (from 1950 to 2004). This indicated that \( T_{\text{max}} \) increased at a faster rate after 1990 in the Northern Hemisphere, and the Northern Hemisphere was experiencing the great warming in winter. At the regional scale, Ding et al. [41] also pointed out that northern China experienced the greatest warming in winter. Shen et al. [22] examined the spatiotemporal variation in temperature in China based on meteorological stations and found that the magnitudes of change for \( T_{\text{max}} \) and \( T_{\text{min}} \) were the greatest in winter. The results from this study (i.e., the greatest increase of \( T_{\text{max}} \) and \( T_{\text{min}} \) in winter) are consistent with those in previous studies. On the other hand, although the magnitudes of change for \( T_{\text{max}} \) and \( T_{\text{min}} \) were the greatest in winter,
the decreasing trend of DTR was the greatest in spring. This is due to the fact that the greatest difference between the trend of $T_{\text{max}}$ and the trend of $T_{\text{min}}$ occurred in spring.

4.2. Possible Causes for Elevation-Dependent DTR Trend

In this study, we found that the annual and seasonal DTR trends were significantly positively correlated with elevation in northeast China. This is possibly due to the fact that solar radiation and greenhouse gases are elevation-dependent. Solar radiation affects the energy between daytime and nighttime, which has a larger effect on $T_{\text{max}}$ than $T_{\text{min}}$ [42,43]. Solar radiation increases with increasing elevation, resulting in a warming temperature at high elevations compared to at low elevations. Therefore, solar radiation has a warming effect on temperature at high elevation. On the other hand, greenhouse gases influence temperature by absorbing longwave radiation [44]. Different from solar radiation, greenhouse gas concentrations decrease with increasing elevation, resulting in a warming temperature at low elevations compared to at high elevation. Therefore, greenhouse gases have a cooling effect on temperature at high elevation.

As shown in Figure 4, elevation was significantly positively correlated with the annual $T_{\text{max}}$ trend and insignificantly correlated with the annual $T_{\text{min}}$ trend in northeast China. As mentioned above, the warming effect caused by solar radiation could be the dominant factor. Sunshine duration worked as a proxy for analyzing the relationship between solar radiation and elevation [45,46]. The results of correlation analysis indicate that the annual trend of sunshine duration was significantly correlated with elevation and the annual trend of $T_{\text{max}}$ (Figure 5 and Table 4). Furthermore, there was a significant correlation between the annual $T_{\text{max}}$ trend and elevation. These indicated that increasing elevation had a warming effect on $T_{\text{max}}$ due to the warming effect of solar radiation. Due to the insignificant correlation between the annual $T_{\text{min}}$ trend and elevation, increasing elevation had a warming effect on DTR.

Table 4. Correlation coefficient between the trend of SD and the trends of $T_{\text{max}}$, $T_{\text{min}}$, and DTR at annual and seasonal scales in northeast China during 1961–2015.

|          | $T_{\text{max}}$ | $T_{\text{min}}$ | DTR  |
|----------|------------------|------------------|------|
| Spring   | 0.305 *          | 0.234            | 0.148|
| Summer   | 0.497 **         | 0.014            | 0.364**|
| Autumn   | 0.24 *           | −0.096           | 0.185|
| Winter   | 0.081            | −0.311 **        | 0.355**|
| Annual   | 0.398 **         | −0.214           | 0.345**|

* Significant at $p < 0.05$, ** Significant at $p < 0.01$.

During spring, summer, and autumn, similar to the results of the annual analysis, the warming effect caused by solar radiation is the dominant factor to cause the elevation-dependent DTR trend. In summer, we found that the correlation between the $T_{\text{max}}$ trend and elevation was the most significant. This is due to the fact that solar radiation is the strongest in summer, which has the strongest warming effect (Table 4). The greenhouse gas concentration is the lowest in summer, which has the weakest cooling effect. The correlation between trend of solar radiation and elevation was the most significant in summer, leading to the most significant correlation between the $T_{\text{max}}$ trend and elevation in summer. On the other hand, we also found a weak correlation between the $T_{\text{min}}$ trend and elevation in summer (Table 4). This could be due to the fact that the increase of temperature during daytime can be extended to nighttime [22]. There was significant negative correlation between the $T_{\text{min}}$ trend and elevation in winter. Different from other seasons, the cooling effect caused by greenhouse gases could be a dominant factor. As anthropogenic activities are gradually intensifying, greenhouse gas emissions are highest in winter [47]. The greenhouse gas concentration at low elevation is much greater than that at high elevation in winter [48], indicating that the warming trend at low elevation is relatively greater as compared with at high elevation. The cooling effect caused by greenhouse gases was greater than the warming effect caused by solar radiation. Therefore,
there was significant negative correlation between the $T_{\text{min}}$ trend and elevation in winter. On the other hand, the warming effect caused by solar radiation may be relatively weaker during daytime than the cooling effect caused by greenhouse gases, leading to insignificant correlation between the $T_{\text{max}}$ trend and elevation in winter. As a consequence, similar to in other seasons, we also found increasing elevation had a warming effect in DTR.

Figure 5. The relationship between the sunshine duration trend and elevation at seasonal (a–d) and annual (e) scales in northeast China during 1961–2015. “SD” represents sunshine duration. * Significant at $p < 0.05$, ** Significant at $p < 0.01$.

5. Conclusions

In this study, we examined the DTR trend and its relationship with elevation in northeast China from 1961 to 2015 by using available data recorded from 68 meteorological stations. The results show that $T_{\text{max}}$ and $T_{\text{min}}$ in northeast China increased significantly at rates of 0.209 and 0.454 °C/decade, respectively. As a result, DTR in northeast China decreased significantly at a rate of 0.252 °C/decade from 1961 to 2015. This is due to the fact that the increase of $T_{\text{min}}$ is faster than the increase of $T_{\text{max}}$. At the seasonal scales, the increase rates of $T_{\text{min}}$ were greater than those of $T_{\text{max}}$ in all seasons, leading to a
significant decrease of DTR in all seasons. The decrease rates of DTR were the greatest in spring (−0.317 °C/decade) and the lowest in summer (−0.173 °C/decade). \( T_{\text{max}} \) increased insignificantly in spring and summer, but significantly in summer and autumn. By contrast, \( T_{\text{min}} \) increased significantly in all seasons.

\( T_{\text{max}} \) tendency rate increased significantly with increasing elevation, leading to significant increase of the DTR trend with increasing elevation at the annual scale. Seasonally, it was also found that the DTR trend increased significantly with increasing elevation. The greatest elevation gradient of the DTR trend occurred in winter (0.392 °C/decade/km). The lowest elevation gradient of the DTR trend occurred in spring (0.209 °C/decade/km). In spring, summer, and autumn, the elevation-dependent DTR trend increased significantly with increasing elevation. However, in winter, the elevation-dependent DTR trend decreased significantly with an increase of elevation. Solar radiation increased with increasing elevation, which had a warming effect on temperature. The greenhouse gas concentration decreased with increasing elevation, which had a cooling effect on temperature. The warming and cooling effects may cancel each other out, resulting in significant correlation between the DTR trend and elevation at the annual and seasonal scales.
