Probabilistic Analysis of Linear Programming Decoding

Constantinos Daskalakis\textsuperscript{1}, Alexandros G. Dimakis\textsuperscript{1}, Richard M. Karp\textsuperscript{1}, and Martin J. Wainwright\textsuperscript{1,2}

Abstract—We initiate the probabilistic analysis of linear programming (LP) decoding of low-density parity-check (LDPC) codes. Specifically, we show that for a random LDPC code ensemble, the linear programming decoder of Feldman et al. succeeds in correcting a constant fraction of errors with high probability. The fraction of correctable errors guaranteed by our analysis surpasses previous non-asymptotic results for LDPC codes, and in particular exceeds the best previous finite-length result on LP decoding by a factor greater than ten. This improvement stems in part from our analysis of probabilistic bit-flipping channels, as opposed to adversarial channels. At the core of our analysis is a novel combinatorial characterization of LP decoding success, based on the notion of a generalized matching. An interesting by-product of our analysis is to establish the existence of “probabilistic expansion” in random bipartite graphs, in which one requires only that almost every (as opposed to every) set of a certain size expands, for sets much larger than in the classical worst-case setting.

Keywords: Error-control coding; channel coding; binary symmetric channel; factor graphs; sum-product algorithm; linear programming decoding; low-density parity check codes; randomized algorithms; expanders.

I. INTRODUCTION

Low-density parity-check (LDPC) codes are a class of sparse binary linear codes, first introduced by Gallager [15], and subsequently studied extensively by various researchers [22], [23], [21]. See the book by Richardson and Urbanke [24] for a comprehensive treatment of the subject. When decoded with efficient iterative algorithms (e.g., the sum-product algorithm [20]), suitably designed classes of LDPC codes yield error-correcting performance extremely close to the Shannon capacity of noisy channels for very large codes [6]. Most extant methods for analyzing the performance of iterative decoding algorithms for LDPC codes—notably the method of density evolution [21], [23]—are asymptotic in nature, based on exploiting the high girth of very large random graphs. Therefore, the thresholds computed using density evolution are only estimates of the true algorithm behavior, since they assume a cycle-free message history. In fact, the predictions of such methods are well-known to be inaccurate for specific codes of intermediate block length (e.g., codes with a few hundreds or thousands of bits). For this reason, our current understanding of practical decoders for smaller codes, which are required for applications with delay constraints, is relatively limited.

The focus of this paper is the probabilistic analysis of linear programming (LP) decoding, a technique first introduced by Feldman et al. [10], [14] as an alternative to iterative algorithms for decoding LDPC codes. The underlying idea is a standard one in combinatorial optimization—namely, to solve a particular linear programming (LP) relaxation of the integer program corresponding to maximum likelihood (optimal) decoding. Although the practical performance of LP decoding is comparable to message-passing decoding, a significant advantage is its relative amenability to non-asymptotic analysis. Moreover, there turn out to be a number of important theoretical connections between the LP decoding and standard forms of iterative decoding [19], [31]. These connections allow theoretical insight from the LP decoding perspective to be transferred to iterative decoding algorithms.

A. Previous work

The technique of LP decoding was introduced for turbo-like codes [10], extended to LDPC codes [11], [14], and further studied by various researchers (e.g., [28], [5], [12], [8], [13], [16]). Significant recent interest has focused on post-processing algorithms that use the ML-certificate property of LP decoding to achieve near ML performance (see [8], [4]) and also [9], [26]).

For concatenated expander codes, Feldman and Stein [13] showed that LP decoding can achieve capacity; see also [1], [18]. For the standard LDPC codes used in practice, the best positive result from previous work [12] is the existence of a constant $\beta > 0$, depending on the rate of the code, such that LP decoding can correct any bit-flipping pattern consisting of at most $\beta n$ bit flips. (In short, we say that LP decoding can correct a $\beta$-fraction of errors.) As a concrete example, for suitable classes of rate 1/2 LDPC codes, Feldman et al. [12] established that $\beta = 0.000177$ is achievable. However, this analysis [12] was worst-case in nature, essentially assuming an adversarial channel model. Such analysis yields overly conservative predictions for the probabilistic channel models that are of more practical interest. Consequently, an important direction—and the goal of this paper—is to develop methods for finite-length and average-case analysis of the LP decoding method.
B. Our contributions

This paper initiates the average-case analysis of LP decoding for LDPC codes. In particular, we analyze the following question: what is the probability, given that a random subset of \(\alpha n\) bits is flipped by the channel, that LP decoding succeeds in recovering correctly the transmitted codeword? As a concrete example, we prove that for bit-degree-regular LDPC codes of rate 1/2 and a random error pattern with \(\alpha n\) bit flips, LP decoding will recover the correct codeword, with probability converging to one for all \(\alpha\) up to at least 0.002. This guarantee is roughly ten times higher than the best guarantee from prior work [12], derived in the setting of an adversarial channel. Our proof is based on analyzing the dual of the decoding linear program and obtaining a simple graph-theoretic condition for certifying a zero-valued solution of the dual LP, which (by strong duality) ensures that the LP decoder recovers the transmitted codeword. We show that this dual witness has an intuitive interpretation in terms of the existence of hyperflow from the flipped to the unflipped bits. Although this paper focuses exclusively on the binary symmetric channel (BSC), the poison hyperflow is an exact characterization of LP decoding for any memoryless binary input symmetric output (MBIOS) channel. We then show that such a hyperflow witness exists with high probability under random errors in the bit-degree-regular LDPC ensemble. The argument itself entails a fairly delicate sequence of union bounds and concentration inequalities, exploiting expansion and matchings on random bipartite graphs.

C. Probabilistic Expanders

An interesting by-product of our analysis is the proof of the existence of probabilistic expanders—that is, bipartite graphs in which almost all sets of vertices of size up to \(\alpha n\) and their subsets have large expansion. One key point is that it is not sufficient to require a random subset of vertices to expand w.h.p., because we use the expansion combined with Hall’s theorem to guarantee large matchings. What we need instead is that a random subset of vertices and all its subsets will expand w.h.p. which by Hall’s theorem will guarantee that a random subset will have a matching. In effect, by relaxing the expansion requirement from every set to almost all sets of a given size, we show that one can obtain much larger expansion factors, and corresponding stronger guarantees on error correction. Our analysis relies on the fact that a random bipartite graph, conditioned on all the small sets having some expansion, will also have this probabilistic expansion for much larger constants \(\alpha\). This innovation allows us to go beyond the worst-case fraction of errors guaranteed by traditional expansion arguments [12], [25].

The remainder of the paper is organized as follows. We begin in Section II with background on error-control coding and low-density parity-check codes, as well as the method of linear programming (LP) decoding. Section III describes our main result and Section IV provides the proof in a series of lemmas, with more technical details deferred to the appendix. We conclude in Section V with a discussion.

II. BACKGROUND AND PROBLEM FORMULATION

We begin with some background on low-density parity-check codes. We then describe the LP decoding method, and formulate the problem to be studied in this paper.

A. Low-density parity-check codes

The purpose of an error-correcting code is to introduce redundancy into a data sequence so as to achieve error-free communication over a noisy channel. Given a binary vector of length \(k\) (representing information to be conveyed), the encoder maps it onto a codeword, corresponding to a binary vector of length \(n > k\). The code rate is given by \(R = k/n\), corresponding to the ratio of information bits to transmitted bits. In a binary linear code, the set of all possible codewords corresponds to a subspace of \(\{0,1\}^n\), with a total of \(2^k\) elements (one for each possible information sequence). The codeword is then transmitted over a noisy channel. In this paper, we focus on the binary symmetric channel (BSC), in which each bit is flipped independently with probability \(\alpha\). Given the received sequence from the channel, the goal of the decoder is to correctly reconstruct the transmitted codeword (and hence the underlying information sequence).

Any binary linear code can be described as the null space of a parity check matrix \(H \in \{0,1\}^{(n-k)\times n}\); more concretely, the code \(C\) is given by the set of all binary strings \(x \in \{0,1\}^n\) such that \(Hx = 0\) in modulo two arithmetic. A convenient graphical representation of such a binary linear code is in terms of its factor graph [20]. The factor graph associated with a code \(C\) is a bipartite graph \(G = (V,C)\), with \(n = |V|\) variable nodes corresponding to the codeword bits (columns of the matrix \(H\)), and \(m = n-k = |C|\) nodes corresponding to the parity checks (rows of the matrix \(H\)). Edges in the factor graph connect each variable node to the parity checks that constrain it, so that the parity check matrix \(H\) specifies the adjacency matrix of the graph. A low-density parity-check code is a binary linear code that can be expressed with a sparse factor graph (i.e. one with \(\Theta(1)\) edges per row).

Given a received sequence \(y\) from the BSC, the maximum likelihood (ML) decoding problem is to determine the closest codeword (in Hamming distance). It is well known that ML decoding for general binary linear codes is NP-hard [2], which motivates the study of sub-optimal but practical algorithms for decoding.

B. LP decoding

We now describe how the problem of optimal decoding can be reformulated as a linear program over the codeword polytope, i.e. the convex hull of all codewords of the code \(C\). For every bit \(y_i\) of the received sequence \(y\), define its log-likelihood as \(\gamma_i = \log \left(\frac{Pr[y_i = 0|y]}{Pr[y_i = 1|y]}\right)\), where \(y_i\) represents the corresponding bit of the transmitted codeword \(y\). Using the
memoryless property of the channel, it can be seen that the maximum likelihood (ML) codeword is

$$\hat{y}_{\text{ML}} = \arg \min_{y \in \mathbb{C}} \sum_{i=1}^{n} \gamma_i y_i. \quad (1)$$

Without changing the outcome of the maximization, we can replace the code $\mathcal{C}$ by its convex hull $\text{conv}(\mathcal{C})$, and thus express ML decoding as the linear program

$$\hat{y}_{\text{ML}} = \arg \min_{y \in \text{conv}(\mathcal{C})} \sum_{i=1}^{n} \gamma_i y_i. \quad (2)$$

Although we have converted the decoding problem from an integer program to a linear program, it remains intractable because for general factor graphs with cycles, the codeword polytope does not have a concise description.

A natural approach, and one that is standard in operations research and polyhedral combinatorics, is to relax the linear program by taking only a polynomial set of constraints that approximate the codeword polytope $\text{conv}(\mathcal{C})$. The first-order LP decoding method [14] makes use of a relaxation that results from looking at each parity check, or equivalently at each row of $H$, in an independent manner. For each check $a \in C$ in the code, denote by $C_a$ the set of binary sequences that satisfy it—that is, $C_a$ corresponds to the local parity check subcode defined by check $a$ and its bit neighbors. Observe that the full code $\mathcal{C}$ is simply the intersection of all the local codes, and the codeword polytope has the exact representation $\text{conv}(\mathcal{C}) = \text{conv}(\bigcap_{a \in C} C_a)$. The first-order LP decoder simply ignores interactions between the various local codes, and performs the optimization over the relaxed polytope given by $P := \bigcap_{a \in C} \text{conv}(C_a)$. Note that $P$ is a convex set that contains the codeword polytope $\text{conv}(\mathcal{C})$, but also includes additional vertices with fractional coordinates (called pseudocodewords in the coding literature). It can be shown [31] that if the LDPC graph had no cycles and hence were tree-structured, this relaxation would be exact; consequently, this relaxation can be thought of as tree-based.

In sharp contrast to the codeword polytope for a general factor graph with cycles, the relaxed polytope $P$ for LDPC codes is always defined by a linear number of constraints. Consequently, LP decoding based on solving the relaxed linear program

$$\hat{y}_{LP} = \arg \min_{y \in \mathbb{P}} \sum_{i=1}^{n} \gamma_i y_i. \quad (3)$$

can solved exactly in polynomial time using standard LP solvers (e.g., interior point or simplex methods), or even faster with iterative methods tailored to the problem structure [11], [29], [30], [31].

For completeness, we now provide an explicit inequality description of the relaxed polytope $P$. For every check $a$ connected to neighboring variables in the set $N(a)$ and for all subsets $S \subseteq N(a)$, $|S|$ odd, we introduce the following constraints

$$\sum_{i \in N(a) \setminus S} y_i + \sum_{i \in S} (1 - y_i) \geq 1. \quad (4)$$

Each such inequality corresponds to constraining the $\ell_1$ distance of the polytope from the sequences not satisfying check $a$—the forbidden sequences—to be at least one. It can be shown that these forbidding inequalities do not exclude valid codewords from the relaxed polytope. We also need to add a set of $2n$ box inequalities—namely, $0 \leq y_i \leq 1$—in order to ensure that we remain inside the unit hypercube. The set of forbidding inequalities along with the $[0,1]$-box inequalities define the relaxed polytope.

Note that, given a check $a$ of degree $d_a$, there are $2^{d_a-1}$ local forbidden sequences, i.e. sequences of bits in the check neighborhood $N(a)$ that do not satisfy the check $a$. Consequently, for a constant check degree code, the total number of local forbidden sequences is $2^{d_a-1}m$, so that number of forbidding inequalities scales linearly in the block length $n$. Fortunately, in the case of low-density parity-check codes, the degree $d_a$ is usually either a fixed constant (for regular constructions) or small with high probability (for irregular constructions) so that the number of local forbidden sequences remains small. Overall, in the cases of practical interest, the relaxed polytope can be characterized by a linear number of inequalities in the way that we have described. (We refer the interested reader to [14], [32] for alternative descriptions more suitable for the case of large $d_a$.)

III. MAIN RESULT AND PROOF OUTLINE

In this section, we state our main result characterizing the performance of LP decoding for a random ensemble of LDPC codes, and provide an outline of the main steps. Section IV completes the technical details of the proof.

A. Random code ensemble

We consider the random ensemble of codes constructed according to the following procedure. Given a code rate $R \in (0,1)$, form a bipartite factor graph $G = (V, C)$ with a set of $n = |V|$ variable nodes, and $m = |C| = \lfloor (1-R)n \rfloor$ check nodes as follows: (i) Fix a variable degree $d_v \in \mathbb{N}$; and (ii) For each variable $j \in V$, choose a random subset $N(j)$ of size $d_v$ from $C$, and connect variable $j$ to each check in $N(j)$. For obvious reasons, we refer to the resulting ensemble as the bit-degree-regular random ensemble, and use $\mathcal{C}(d_v)$ to denote a randomly-chosen LDPC code from this ensemble.

The analysis of this paper focuses primarily on the binary symmetric channel (BSC), in which each bit of the transmitted codeword is flipped independently with some probability $\alpha$. By concentration of measure for the binomial distribution, it is equivalent (at least asymptotically) to assume that a constant fraction $\alpha n$ of bits are flipped by the channel. Let $\mathbb{P}$ denote the joint distribution, over both the space of bit-degree-regular random codes, and the space of $\alpha n$ bit flips. With the goal of obtaining upper bounds on the LP error probability $\mathbb{P}[\text{LP fails}]$, our analysis is based on the expansion of the factor graph of the code. Specifically, the factor graph of a code with blocklength $n$ is a $(\mu, \rho)$-expander if all sets $S$ of variable nodes, of size $|S| \leq \mu n$, are connected to at least $\rho |S|$ checks.

\footnote{Throughout this paper, we work with codes with simple parity check constraints (LDPC codes) which are different from the generalized expander codes [25],[13] that can have large linear subcodes as constraints.}
B. Statement of main result

Our main result is a novel bound on the probability of error for LP decoding, applicable for finite block length $n$ and the bit-degree-regular LDPC ensemble. The main idea is to show that, under certain expansion properties of the code, LP decoding will succeed in recovering the correct codeword with high probability. We note that a random graph will have the required expansion properties with high probability.

In particular, we show that for the joint distribution over random expander bit-degree-regular codes and $[\alpha_v,n]$ (or less) bit flips by the channel, there exists a constant $\alpha_c$, depending on the expansion properties of the ensemble, such that LP decoding succeeds with high probability. More formally,

**Theorem 1:** For every bit-degree-regular LDPC code ensemble with parameters $R, d_v, n$, we specify quadruples $(\alpha_c,c,\mu,p)$ for which the LP decoder succeeds with high probability over the space of bit-degree-regular random codes and at most $[\alpha_v,n]$ bit flips. The probability of failure decreases exponentially in $c$—namely

$$\Pr[\text{LP success} \mid C(d_v) \text{ is an } (\mu,p) \text{ expander}] \geq 1 - e^{-cn}.$$  \hspace{1cm} (5)

We note that any factor graph sampled from the bit-regular ensemble will be an expander with high probability. In general, the fraction of correctable errors $\alpha_c$ guaranteed by Theorem 1 is a function of the code ensemble, specified by the code rate $R$, the bit degree $d_v$, its expansion parameters $\mu$ and $p$ and the error exponent $c$. For any code rate, the maximum fraction of correctable errors $\alpha_c$ achieved by our analysis is provably larger than that of the best previously known result [12] for LP decoding, which guaranteed correction of a fraction $\frac{2q^2-2}{2q^2} \mu$ of errors. As a particular illustration of the stated Theorem 1 we have the following guarantee for rate $R = \frac{1}{2}$ codes:

**Corollary 1:** For code rate $R = \frac{1}{2}$, bit degree $d_v = 8$ and error fraction $\alpha_c \in (0, 0.002)$, the LP decoder succeeds with probability $1 - o(1)$ over the space of bit-degree-regular random codes of degree $d_v$ and $[\alpha_v,n]$ bit flips. More generally, for any code rate $R$, our analysis in Section IV (see discussion following Lemma 8) specifies conditions for the bit flipping probability $\alpha_c$ and the expansion parameters $\mu$ and $p$ so that the condition (5) is satisfied with a suitable choice of error exponent $c$.

C. Outline of main steps

We now describe the main steps involved in the proof of Theorem 1.

1) Hyperflow witness: As in previous work [12], we prove that the LP decoder succeeds by constructing a dual witness: a dual feasible vector with zero dual cost, which guarantees that the transmitted codeword is optimal for the primal linear program. Using the symmetry of the relaxed polytope, it can be shown [14] that the failure or success of LP decoding depends only on the subset of bits flipped by the channel and not on the transmitted codeword. Consequently, we may assume without loss of generality that the all zero codeword was transmitted. Moreover, note that, for the binary symmetric channel (BSC) with flip probability $\epsilon$, the log-likelihood of each received bit is either $\log \left( \frac{1-\epsilon}{\epsilon} \right)$ or $-\log \left( \frac{1-\epsilon}{\epsilon} \right)$. Since the optimum of the primal is not affected by rescaling, we may assume without loss of generality that all $\gamma_i$ are either 1 or -1. Then, every flipped bit $i$ will be assigned $\gamma_i = -1$, whereas every unflipped bit $\gamma_i = 1$. Under these assumptions, Feldman et al. [12] demonstrated that a dual witness can be graphically interpreted as a set of weights on the edges of the factor graph of the code:

**Lemma 1 (Dual witness [12]):** Suppose that all bits in the set $F$ are flipped by the channel, whereas all bit in the complementary set $F^c := V \setminus F$ are left unchanged. Set $\gamma_i = -1$, for all $i \in F$, and $\gamma_i = 1$, for all $i \in F^c$. Then linear programming (LP) decoding succeeds for this error pattern if there exist weights $\tau_{ia}$ for all checks $a \in C$ and distinct adjacent bits $i \in N(a)$ such that the following conditions hold:

$$\tau_{ia} + \tau_{ja} \geq 0 \quad \forall \text{ checks } a \in C, \text{ and }$$

$$\tau_{ia} < \gamma_i \quad \forall \text{ adjacent bits } i, j \in N(a).$$  \hspace{1cm} (6a)

$$\sum_{a \in N(i)} \tau_{ia} < \gamma_i \quad \forall i \in V.$$  \hspace{1cm} (6b)

We next introduce a sufficient condition for the success of LP decoding, one which is equivalent but arguably more intuitive than the dual witness definition:

**Definition 1:** A hyperflow for $\gamma$ is a set of edge weights $\tau_{ij}$ that satisfy condition (6b) and moreover, have the following additional property: for every check $j \in C$, there exists a $P_j \geq 0$ such that for exactly one variable $i \in N(j)$, $\tau_{ij} = -P_j$ and for all the other $i' \in N(j) \setminus \{i\}$, $\tau_{i'j} = P_j$.

The flow interpretation is that each check corresponds to a hyperedge connecting its adjacent variables; the function of any check is to replicate the flow incoming from one variable towards all its other adjacent variables. With this setup, condition (6b) corresponds to the requirement that all the variables $i$ with $\gamma_i < 0$ need to get rid of at least $-\gamma_i$ units of “poison”, whereas each variable $i$ with $\gamma_i > 0$ can absorb at most $\gamma_i$ units of “poison”. Figure II illustrates a valid hyperflow for a simple code.

We claim that the existence of a valid hyperflow is equivalent to the dual witness:

**Proposition 1:** There exists a weight assignment $\tau_{ij}$ satisfying the conditions of Lemma 1 if and only if there exists a hyperflow $\tau'_{ij}$ for $\gamma$.

See Appendix A for a proof of this claim.

2) Hyperflow from $(p,q)$ matching: Let $N(F)$ denote the subset of checks that are adjacent to the set $F$ of flipped bits. One way to construct a hyperflow for $\gamma$ is to match each bit $i$ in the set $F$ of flipped bits, with some number of checks, say $p \leq d_v$, checks, to which it has the exclusive privilege to push flow, suppose in a uniform fashion. This follows because in a matching each check is used at most once. Let us refer to the checks that are actually used in such a matching as dirty, and to all the checks in $N(F)$ as potentially dirty. The challenge is that there might be unflipped variables that are adjacent to a large number of dirty checks, and hence fail to satisfy condition (6b): i.e. they receive more flow than they can absorb. Thus, the goal is to construct the matching of
Each bit refined combinatorial object that we call a too many dirty neighbors. The flipped bits in a careful way so that no unflipped bit has its edges adjacent to checks in (a) each bit $p, q$.

Definition 2: Given non-negative integers $p$ and $q$, a $(p,q)$-matching is defined by the following conditions:

(a) each bit $i \in F$ must be matched with $p$ distinct checks, and
(b) each bit $j \in F^c$ must be matched with

$$X_j := \max\{q - d_v + Z_j, 0\} \quad (7)$$

distinct checks from the set $N(F)$.

In all theoretical analysis in this paper, it is technically convenient to consider only pairs $(p,q)$ such that

$$p \geq q, \quad 2p + q > 2d_v, \quad \text{and} \quad d_v \geq p + 2.$$

(The lone exception is Figure 2 which is shown only for illustrative purposes.)

We refer to the number of checks with which each variable node needs to be matched as its request number. In this language, all flipped bits have $p$ requests while each unflipped bit $j$ has a variable number of requests $X_j$ which depends on how many of its edges land on checks which have flipped neighbors. The following lemma justifies why requests are selected in this way and illustrates the key property of the $(p,q)$-matching:

**Lemma 2:** A $(p,q)$-matching guarantees that all the flipped bits are matched with $p$ checks, and all the non-flipped bits have $q$ or more non-dirty check neighbors.

This fact follows by observing that any unflipped bit $j$ with $Z_j$ edges in $N(F)$ has $d_v - Z_j$ clean neighboring checks, and requests $q - (d_v - Z_j)$ extra checks from the potentially dirty ones.

Figure 2 illustrates a generalized matching for a degree $d_v = 4$ factor graph, and $(p,q) = (2,3)$. Note that the bit node labeled 2 has $Z_2 = 3$ neighbors in the potentially dirty set $N(F)$, and so it makes $X_2 = 3 - (4 - 3) = 2$ requests for matching. This ensures that it is connected to $2+1 = q$ checks that are not dirty. A similar argument applies to bit 1, with $Z_1 = 2$ and $X_1 = 1$.

We next claim that a $(p,q)$-matching is a certificate of LP decoding success:

**Lemma 3:** For any integers $p$ and $q$ such that $2p + q > 2d_v$, a $(p,q)$-matching can be used to generate a set of weights $\tau_{i\alpha}$ which constitute a hyperflow for $\gamma$ and, hence, satisfy the dual witness conditions $[4]$.

**Proof:** Each flipped bit is matched with $p$ checks: suppose it sends $\chi$ units of poison to each of these checks. In the worst case, the remaining $d_v - p$ edges are connected to checks to which other flipped bits are sending poison. Therefore, each flipped bit (in the worst case) can purge itself of $p\chi - (d_v - p)\chi$ units of its own poison, so that we require that $p\chi - (d_v - p)\chi > 1$.

By Lemma 2, each unflipped bit has at least $q$ checks that do not send any poison. In the worst case, then, an unflipped bit can receive $(d_v - q)\chi$ units of poison, which we require to be less than 1. Overall, a valid routing parameter $\chi$ will exist.

![Figure 1](image1.png)  
**Figure 1.** Example of a valid hyperflow: bits $x_1$ and $x_2$ have been flipped in a binary symmetric channel, and hence each are contaminated with one unit of poison. Each of the unflipped bits can absorb up to one unit of poison, whereas the checks act as hyper-edges and replicate any incoming flow in all directions other than the incoming one. The valid hyperflow shown in this figure certifies that LP decoding can correct these two flipped bits.

![Figure 2](image2.png)  
**Figure 2.** Illustration of a $(p,q)$-generalized matching with $p = 2$, $q = 3$ and $d_v = 4$. The first three bits are flipped, and form the poisoned set $S$: each flipped bit must be matched with $p = 2$ checks from its neighborhood (edges drawn with arrows). The bit node labeled 2 lies in $S$: it connects to $Z_2 = |N(2) \cap N(F)| = 3$ checks within the set $N(F)$, and so must be matched with $X_2 = q - (d_v - 3) = 2$ checks from $N(F)$ (two incoming arrows). By construction, bit 2 then has $2 + 1 = q$ checks that are not contaminated. Similarly, bit 1 connects $Z_1 = 2$ checks from $N(F)$, and so must be matched with $X_1 = q - (d_v - 2) = 1$ check from $N(F)$ (incoming arrow). It has a total of $1 + 2 = q$ checks that are not contaminated.
if $\frac{1}{2p-d_v} < \frac{1}{d_v-q}$, or equivalently, if $p + q > 2d_v$ as claimed.

In fact, it can verified that our combinatorial witness for LP decoding success is easier to satisfy than the condition used by Feldman et al. [12]. Our use of this improved witness, along with our focus on the probabilistic setting, are the two ingredients that allow us to establish a much larger fraction $\alpha_c$ of correctable errors.

3) From expansion to matching via Hall’s theorem: The remainder (and bulk) of the analysis involves establishing that, with high probability over the selection of random expander bit-degree-regular codes and random subsets of $[\alpha n]$ flipped bits, a $(p, q)$-matching exists, for suitable values $q \leq p$ to be specified later. It is well known [3], [25] that random regular bipartite graphs will have good expansion, with high probability:

**Lemma 4 (Good expansion):** For any fixed code rate $R \in (0, 1)$, degree $d_v$, and $p \leq d_v - 2$, there exist constants $\mu, c > 0$ so that a code $C(d_v)$ from the bit-degree-regular ensemble of degree $d_v$ is a $(\mu n, p)$ expander with probability at least $1 - O(1/n)$.

Therefore, conditioned that the event that the random graph is an expander, the next step is to analyze the existence of a $(p, q)$-matching. We use Hall’s theorem [27], which in our context, states that a matching exists if and only if every subset of the variable nodes have (jointly) enough neighbors in $N(F)$ to cover the sum of their requests.

Given our random graph and channel models, an equivalent description of the neighborhood choices for each variable $j \in F^c$ is as follows. Each node $j \in F^c$ picks a random number $Z_j \in \{0, 1, \ldots, d_v\}$ according to the binomial distribution $\text{Bin}(d_v, \frac{\mu n}{m})$, and picks a subset of $N(F)$ of size $Z_j$. This subset corresponds to the intersection of its check neighborhood $N(j)$ with the check neighborhood $N(F)$ of the flipped bits. The remaining $d_v - Z_j$ edges from bit $j$ connect to checks outside $N(F)$. With this set-up, we now define the a “bad event” $\mathcal{E}$, defined by the existence of a pair $(S_1, S_2) \subseteq 2^F \times 2^{F^c}$ of sets that contracts, meaning that it has more requests than neighbors, so that

$$|N(S_1) \cup N(S_2) \cap N(F)| < p|S_1| + \sum_{j \in S_2} \max\{0, q - (d_v - Z_j)\}. \quad (8)$$

Notice that only the neighbors in $N(F)$ are counted, since a $(p, q)$-matching involves only checks in $N(F)$. By Lemma 4 the event $\mathcal{E}$ must occur whenever LP decoding fails so that we have the inequality $\mathbb{P}[\text{LP decoding fails}] \leq \mathbb{P}[\mathcal{E}]$. Defining the event

$$\mathcal{G}(d_v, \mu, p) := \{C(d_v) \text{ is a } (\mu n, p) \text{ expander}\}, \quad (9)$$

we make use of the following conditional form of this inequality:

$$\mathbb{P}[\text{LP decoding fails} | \mathcal{G}] \leq \mathbb{P}[\mathcal{E} | \mathcal{G}]. \quad (10)$$

However, all subsets of variable nodes of size at most $\mu n$ in a $(\mu n, p)$ expander have a $p$-matching and, because $q \leq p$, it follows that

$$\mathbb{P}[\mathcal{E}(A_i) | \mathcal{G}] = 0. \quad (11)$$

Consequently, we only have to deal with the remaining two terms of the summation for $i = 2$ and $i = 3$. Before proceeding, an important side-remark here is that equation (11) by itself implies that the LP decoder can correct a constant fraction of errors; indeed, it is precisely this observation that was exploited by Feldman et al. [12]. However, our ultimate goal in this paper is to establish higher fractions of correctable errors, so we need to continue our analysis further.
For \( i = 2, 3 \), we have
\[
\mathbb{P}[\mathcal{E}(A_i) \mid \mathcal{G}] = \frac{\mathbb{P}[\mathcal{E}(A_i) \land \mathcal{G}]}{\mathbb{P}[\mathcal{G}]} \leq \frac{\mathbb{P}[\mathcal{E}(A_i)]}{\mathbb{P}[\mathcal{G}]} \leq 2\mathbb{P}[\mathcal{E}(A_i)],
\]
where the last inequality follows from Lemma \ref{lemma}. Overall, putting everything together, we conclude that
\[
\mathbb{P}[\text{LP fails} \mid \mathcal{G}] \leq 2 \sum_{i=2}^{3} \mathbb{P}[\mathcal{E}(A_i)].
\]

The remainder of the proof consists of careful analysis of these two error terms. It turns out to be convenient to use an alternative probabilistic model in the analysis. In particular, observe that there is an inconvenient asymmetry in the definition of our generalized matching: the bits of set \( F^c \) need to be matched with checks from the neighborhood of the flipped bits \( F \), and not from the whole set of checks from which they select their neighbors. This correlation between \( N(F) \) and the number of requests from set \( F^c \) creates severe complications in the analysis. Indeed, any attempt to use Hall’s condition through union bounds seems to require independence among different edges; moreover, crude upper-bounds on the number of requests from set \( F^c \) seem inadequate to decorrelate the requests of \( F^c \) from the size of \( N(F) \). For this reason, we use an alternative probabilistic model, as described in Section \ref{sec:alternative-model}.  

\textbf{IV. PROOF OF THEOREM 1} 

We now turn to the remaining (somewhat more technical) steps involved in the proof of Theorem 1.

\textbf{A. Simplifying the probability model} 

In order to decouple the probability distribution of the requests of \( F^c \) from the size of \( N(F) \), observe that the number of requests \( X_j \) from each bit \( j \) in \( F^c \) grows linearly with the number of edges that this bit has in \( N(F) \). Notice that the checks are selected with replacement and the degree of a variable can be strictly smaller than \( d_v \), although this will not be an issue asymptotically. This observation combined with a coupling argument shows that, if \( x, x' \in \{0, \ldots, d_v\}^{|F^c|} \) are two vectors of requests from the bits in \( F^c \), where \( x \leq x' \) elementwise, then the probability that a \((p,q)\)-matching exists is larger conditioned on \( x \) than on \( x' \).

This observation suggests the following alternative experiment:

- A node \( j \in F^c \) first picks a random number \( Z_j \in \{0,1,\ldots,d_v\} \) according to the modified binomial distribution \( Bin\left(d_v, \frac{\alpha n}{m}\right) \).
- Node \( j \) then chooses \( Z_j \) checks from \( N(F) \) with replacement.

This procedure is repeated independently for each \( j \in F^c \). Since \( |N(F)| \leq d_v \lceil \alpha n \rceil \), the bits of set \( F^c \) will tend to have more edges in \( N(F) \) and, therefore, more requests in this new experiment than in the original one (as suggested by the natural coupling between the two processes). Moreover, since checks are now chosen with replacement, for each bit \( j \in F^c \), the size of the intersection \( N(j) \cap N(F) \) is less than or equal to \( Z_j \), since the same check might be chosen more than once. Intuitively, the existence of matchings is less likely in the new experiment than in the original one; this claim follows rigorously by combining these observations with the coupling argument used in the previous paragraph. The benefit of switching from the original experiment to this new experiment is in allowing us to decouple the process of deciding the number of requests made by each bit in \( F^c \) from the cardinality of the random variable \( N(F) \).

Let us use \( \mathbb{Q} \) to denote the probability distribution over random graphs in this new model. Setting \( F^c(q) = \{ j \in F^c \mid q > d_v - Z_j \} \), we can define the alternative “bad event” \( \mathcal{B} \), meaning that there exist \( S_1 \subseteq F \) and \( S_2 \subseteq \mathcal{F}^c(q) \) such that
\[
|N(S_1) \cup |N(S_2) \cap N(F)|| \leq p|S_1| + \sum_{j \in S_2} |q - (d_v - Z_j)|.
\]

In addition, we define the corresponding sub-events \( \mathcal{B}(A_i) \) for \( i = 1, 2, 3 \). As argued above, it must hold that
\[
\mathbb{P}[\mathcal{E}(A_i)] \leq \mathbb{Q}[\mathcal{B}(A_i)], \quad \text{for all} \quad i = 1, 2, 3,
\]
and, therefore, as inequality \ref{eq:bound} suggests, in order to upper bound the probability of LP decoding failure, it suffices to obtain upper bounds on the probabilities \( \mathbb{Q}[\mathcal{B}(A_i)] \) for \( i = 2, 3 \).

For future use, we define for fixed subsets \( S_1 \subseteq F \) and \( S_2 \subseteq F^c(q) \), the event \( \mathcal{B}(S_1, S_2) \) that equation \ref{eq:bound} holds for \( S_1 \) and \( S_2 \). We now proceed, in a series of steps, to obtain suitable upper bounds on the probabilities \( \mathbb{Q}[\mathcal{B}(A_i)] \) and, hence, on the probability of LP decoding failure.

\textbf{B. Conditioning on requests from \( F^c \)}

For each \( i \in \{1, \ldots, q\} \), we define the random variable
\[
Y_i : = \left\{ j \in F^c \mid Z_j = d_v - (q - i) \right\},
\]
corresponding to the number of bits in \( F^c \) with \( d_v - (q - i) \) edges that lie inside the “contaminated” neighborhood \( N(F) \) and, hence, with \( i \) requests each. Note that each \( Y_i \) is binomial with parameters \( \lfloor (1 - \alpha)n \rfloor \) and
\[
b_i = \binom{d_v}{d_v - q + i} \left( \frac{\alpha n}{m} \right)^{d_v - q + i} \left( 1 - \frac{\alpha n}{m} \right)^{q - i}.
\]

Since \( \mathbb{E}[Y_i] = b_i \lfloor (1 - \alpha)n \rfloor \), applying Hoeffding’s inequality \ref{hoeffding} yields the sharp concentration
\[
\mathbb{Q}[|Y_i - b_i \lfloor (1 - \alpha)n \rfloor| \geq \epsilon_1 n] \leq 2 \exp \left(-2 \epsilon_1^2 n \right)
\]
for any \( \epsilon_1 > 0 \). Hence, if we define the event
\[
T(\epsilon_1) : = \bigcap_{i=1}^{q} \{ |Y_i - b_i \lfloor (1 - \alpha)n \rfloor| \leq \epsilon_1 n \},
\]
then a simple union bound yields that
\[
\mathbb{Q}[T(\epsilon_1)] \geq 1 - 2q \exp \left(-2 \epsilon_1^2 n \right),
\]
so that it suffices to bound the conditional probabilities $Q[B(A_i) \mid T(\epsilon_1)]$, $i = 2,3$. Note that conditioned on the event $T(\epsilon_1)$, we are guaranteed that

$$\frac{Y_i}{n} \leq b_i(1 - \alpha) + \epsilon_1 =: \gamma_i^{up}.$$  (18)

We now turn to bounding the probability of the bad event $B$. Since, by symmetry, the probability of the event $B(S_1, S_2)$ is the same for different sets $S_1$ of the same size, a union bound gives $Q[B(A_2) \mid T(\epsilon_1)] \leq \sum_{s_1 = [\epsilon_2 n]}^{[\alpha n]} D(s_1)$, where

$$D(s_1) := \left[\frac{[\alpha n]}{s_1}\right] \times Q[\exists S_2 \subseteq F^c(q) \text{ with } (S_1, S_2) \in A_2 \text{ s.t. } B(S_1, S_2) \mid T(\epsilon_1)],$$

with $S_1$ is any fixed set of size $s_1$.

Before bounding these terms, we first partition the values of $s_1$ into two sets $\{[\epsilon_2 n], \ldots, [\epsilon_2 n]\}$ and $\{[\epsilon_2 n] + 1, \ldots, [\alpha n]\}$ for some value of $\epsilon$ to be specified formally in Lemma 5. To give some intuition, in the conditional space $T(\epsilon_1)$, the total number of matching-requests from the bits of set $F^c$ is at most

$$V := n \sum_{i=1}^q i \gamma_i^{up}.$$  (19)

Therefore, if $Q[B(A_2) \mid T(\epsilon_1)]$ is indeed small, we would expect that, if the set $S_1$ is large enough (say $|S_1| \approx |F|$), then with high probability, the size of its image $N(S_1)$ should be large enough not only to cover its own requests but also $V$ additional requests—viz. $|N(S_1)| \geq p|S_1| + V$. If this condition holds, then there cannot exist any set $S_2$ such that the event $B(S_1, S_2)$ occurs. We formalize this intuition in the following result, proved in Appendix C.

**Lemma 5 (Upper Regime):** Define $\bar{\gamma} := \sum_{i=1}^q i \gamma_i^{up}$, and the function

$$f(s) := \alpha H\left(\frac{s}{\alpha}\right) + (1 - R) H\left(\frac{ps + \overline{\gamma}}{1 - R}\right) + d_u s \log_2 \left(\frac{ps + \bar{\gamma}}{1 - R}\right),$$

where $H(\cdot)$ is the binary entropy function, and set $\bar{\gamma}_{crit} := \min\{\alpha, \inf\{s \in [0, \alpha] \mid f(s') < 0, \forall s' \in [s, \alpha]\}\}$.  (20)

Then for all $s_1 \in \{[\bar{\gamma}_{crit} n] + 1, \ldots, [\alpha n]\}$, the quantity $D(s_1)$ decays exponentially fast in $n$. It remains to bound $D(s_1)$ for $s_1 \in L_1$, where

$$L_1 := \{[\epsilon_2 n], \ldots, [\bar{\gamma}_{crit} n]\}.$$

For a randomly chosen set $S_1$, define the event $F(s_1, \gamma_1) := \{S_1 = s_1, |N(S_1)| = \gamma_1\}$.  (21)

By conditioning, we have the decomposition $D(s_1) = \sum_{\gamma_1 = 1}^{d_u s_1} E(\gamma_1, s_1)$, where

$$E(\gamma_1, s_1) := \left[\frac{[\alpha n]}{s_1}\right] Q[F(\gamma_1, s_1)] \times Q[\exists S_2 \text{ with } (S_1, S_2) \in A_2 \text{ s.t. } B(S_1, S_2) \mid F(s_1, \gamma_1)].$$

Here $Q'$ denotes the conditional probability distribution of $Q$ conditioned on the event $T(\epsilon_1)$.

The following lemma allows us to restrict our attention to linearly-sized check neighborhoods $N(S_1)$ in analyzing the individual terms $E(\gamma_1, s_1)$ of the summation; the proof is provided in Appendix D.

**Lemma 6 (\bar{\gamma}_{crit} small):** Define the critical point $\bar{\gamma}_{crit}(\bar{\gamma})$

$$\sup\{\bar{\gamma}_1 \in (0, d_u s_1] \mid 2 + d_u s_1 \log_2 \left(\frac{\bar{\gamma}_{1}}{1 - R}\right) < 0\}.$$  (22)

Then, for set sizes $s_1 \geq [\epsilon_2 n]$ and neighborhood sizes $\gamma_1 \leq \bar{\gamma}_{crit}(\epsilon_2 s_1)$, the quantity $E(\bar{\gamma}_1, s_1)$ decays exponentially fast in $n$.

Note that the supremum (22) is always finite. This lemma essentially says that if $s_1$ has linear size, its neighborhood $\gamma_1$ must also have linear size.

To summarize our progress thus far, we first argued that in order to bound the probability $Q[B(A_2) \mid T(\epsilon_1)]$, it suffices to bound the quantities $D(s_1)$, for $s_1 \in \{[\epsilon_2 n], \ldots, [\alpha n]\}$. Next we partitioned the range of $s_1$ into two sets: the lower set $L_1 := \{[\epsilon_2 n], \ldots, [\epsilon_2 n]\}$, and the upper set $U_1 := \{[\bar{\gamma}_{crit} n] + 1, \ldots, [\alpha n]\}$. The upper set has the property that for all sets $S_1 \subseteq F$ of size $|S_1| \leq U_1$, having high probability the neighborhood $N(S_1)$ is big enough to accommodate not only the matching requests from set $S_1$, but also all possible matching-requests from any set $S_2 \subseteq F^c$. Having established this property for large $S_1$ sets, it remains to focus on small $S_1$. In this regime, the neighborhood $N(S_1)$ on its own is no longer sufficient to cover the joint set of requests from $S_1$ and from any possible set $S_2 \subseteq F^c$. Consequently, one has to consider for every choice $(S_1, S_2) \in A_2$, whether the joint neighborhood $N(S_1) \cup (N(S_2) \cap N(F))$ is large enough to cover the matching requests from $S_1$ and $S_2$.

At this point, one might imagine that a rough concentration argument applied to the sizes of $N(S_1)$ and $N(S_2) \cap N(F) \setminus N(S_1)$ would suffice to complete the proof. Unfortunately, any concentration result must be sufficiently strong to dominate the factor $\left(\frac{[\alpha n]}{s_1}\right)$ that leads the expression $D(s_1)$. Consequently, we study the exact distribution of the size of $N(S_1)$, and bound the quantities $E(\gamma_1, s_1)$ for $s_1 \in L_1$ and $\gamma_1 = 1, \ldots, d_u s_1$. Of course, since $s_1$ is linear in size, the bulk of the probability mass is concentrated on linear values for $\gamma_1$. Therefore, by Lemma 4 we need only bound $E(\gamma_1, s_1)$ for $s_1 \in L_1$ and $\gamma_1 \geq \bar{\gamma}_{crit}(\epsilon_2) n$. We complete these steps in the following subsection.

**C. Completing the bound**

Let us fix sizes $s_1 \in L_1$ and $\gamma_1 \geq \bar{\gamma}_{crit}(\epsilon_2) n$. For a set $S_1$ of size $s_1$ with neighborhood $N(S_1)$ of size $\gamma_1$, define its residual neighborhood to be the set $N(F) \setminus N(S_1)$ and use $\gamma_2 := |N(F) \setminus N(S_1)|$ to denote its size. Moreover, define the vector of requests $y \in \{0, \ldots, [\bar{\gamma}_{crit} n]\}$, let us denote by $\beta(s_1, \gamma_1, y)$ the number of checks missing from the neighborhood of $S_1$ to cover the total number of requests from $S_1$ and a set $S_2$ with configuration of requests $y$. Also, let $\nu(y)$

3Recall that we have conditioned on the event $T(\epsilon_1)$, so that the number of bits in $F^c$ with $i$ matching requests is concentrated, for every $i \in \{1, \ldots, q\}$.
be the number of edges from $S_2$ to $N(F)$. More precisely, the quantities $\beta(s_1, \gamma_1, y)$ and $\nu(y)$ are given by the formulae

$$\beta(s_1, \gamma_1, y) := p s_1 - \gamma_1 + \sum_{i=1}^{q} i y_i \quad (23a)$$

$$\nu(y) := \sum_{i=1}^{q} (d_v - q + i) y_i. \quad (23b)$$

Note that for $s_1 \in L_1$ and $\gamma_1 \geq \gamma_{\text{crit}}(\epsilon_2)n,$ the quantity $\beta$ also grows linearly in $n$; as usual, we use $\beta$ to denote the rescaled quantity $\beta/n.$ Also recall the definition of $\tilde{g}_i^{up}$ from equation (18).

Letting $\vec{\gamma} := (\vec{\gamma}_1, \ldots, \vec{\gamma}_q)$ be a vector of request fractions in $[0, 1]^q$, we define

$$G(s_1, \gamma_1, \gamma_2, y) := \sum_{k=1}^{4} \min\{0, G_k(s_1, \gamma_1, \gamma_2, \vec{\gamma})\}$$

where

$$G_1 := \alpha H \left( \frac{\tilde{\gamma}_1}{\alpha} \right) \sum_{i=1}^{q} \tilde{g}_i^{up} H \left( \frac{\tilde{g}_i^{up}}{\tilde{g}_i} \right)$$

$$G_2 := (1 - R)H \left( \frac{\tilde{\gamma}_1}{(1 - R)} \right) + d_v \tilde{\gamma}_1 \log_2 \left( \frac{\tilde{\gamma}_1}{(1 - R)} \right)$$

$$G_3 := ((1 - R) - \gamma_1)H \left( \frac{\tilde{\gamma}_2}{((1 - R) - \gamma_1)} \right) + d_v (\alpha - \gamma_1) \log_2 \left( \frac{\tilde{\gamma}_1 + \tilde{\gamma}_2}{(1 - R)} \right)$$

$$G_4 := \tau_2 H \left( \min\{\tilde{\gamma}_2, \tilde{\beta}(\tilde{\gamma}_1, \gamma_1, \vec{\gamma})\} \right) \tau_2$$

$$+ \nu(\vec{\gamma}) \log_2 \left( \frac{\tilde{\gamma}_1 + \min\{\tilde{\gamma}_2, \tilde{\beta}(\tilde{\gamma}_1, \gamma_1, \vec{\gamma})\}}{\tilde{\gamma}_1 + \tilde{\gamma}_2} \right)$$

With these definitions, we have the following result:

**Lemma 7 (Exponential upper bound):** Suppose that the following inequalities hold:

$$\tilde{\gamma}_{\text{crit}} < \frac{\alpha}{2}. \quad (25a)$$

$$\alpha d_v < (1 - R) - d_v \tilde{\gamma}_{\text{crit}}, \quad \text{and} \quad (25b)$$

$$\alpha H \left( \frac{\tilde{\gamma}_{\text{crit}}}{\alpha} \right) d_v (\alpha - \tilde{\gamma}_{\text{crit}}) \log_2 \left( \frac{d_v \tilde{\gamma}_{\text{crit}}}{(1 - R)} \right) < 0. \quad (25c)$$

Then for some $c > 0$, we have the exponential upper bound

$$\mathbb{P}[B(A_2) \mid T(\epsilon_1)] \leq 2^{\alpha F(\alpha)c n} + \exp(-cn)$$

where the function in the exponent is given by

$$F(\alpha) := \sup_{\vec{\gamma}_1, \vec{\gamma}_2, \vec{\gamma}_1(\vec{\gamma})} G(s_1, \gamma_1, \gamma_2, \vec{\gamma}_1, \ldots, \vec{\gamma}_q). \quad (26)$$

with the maximization over

$$\vec{\gamma}_1 \in [0, \tilde{\gamma}_{\text{crit}}]$$

$$\gamma_1 \in [0, d_v \tilde{\gamma}_1]$$

$$\vec{\gamma}_2 \in [0, d_v (\alpha - \vec{\gamma}_1)]$$

$$\vec{\gamma}_i \in [\tilde{g}_i^{up}/2, \tilde{g}_i^{up}].$$

See Appendix E for a proof of this lemma.

It remains to upper bound the probability of the bad-event $B(A_3)$ which is equivalent to the existence of a pair of contracting sets $(S_1, S_2)$, where the size of set $S_1 \subseteq F$ is at most $\epsilon_2 n$ and the size of set $S_2 \subseteq F^c$ is at least $(\mu - \epsilon_2)n.$ Note that we haven’t yet specified the constant $\epsilon_2$. The following lemma establishes that there exists a value of $\epsilon_2$ so that $\mathbb{P}[B(A_3) \mid T(\epsilon_1)]$ is bounded by an exponentially decreasing function in $n$ provided the function $F(\alpha)$ from equation (26) is negative. The proof of this final lemma is provided in Appendix E.

**Lemma 8:** If $F(\alpha) < 0$, then there exists $\epsilon_2$ so that the probability $\mathbb{P}[B(A_3) \mid T(\epsilon_1)]$ is decreasing exponentially in $n$.

We may now complete the proof of Theorem 1. For a given rate $R$, fix the bit degree $d_v$ and the matching parameters $(p, q)$ such that

$$2p + q > 2d_v, \quad p \geq q, \quad \text{and} \quad d_v - p \geq 2. \quad (27)$$

and recall the definition (20) of $\tilde{\gamma}_{\text{crit}}$. Suppose that the three inequalities (25) hold, and that the function $F$ defined in equation (26) satisfies

$$F(\alpha) < 0 \quad (28)$$

Then the probability

$$\mathbb{P}[\text{LP decoding fails} \mid C(d_v) \text{ is a } (\mu n, p) \text{ expander }]$$

decays exponentially in $n$, where $\mathbb{P}$ is the uniform distribution over the set of bit-degree-regular codes of degree $d_v$ and selections of $[cn]$ bit flips.

In particular, these explicit conditions allow us to investigate fractions of correctable errors on specific code ensembles. As a concrete example, for code rate $R = 1/2$, if we choose variable degrees $d_v = 8$ and generalized matching parameters $(p, q) = (6, 5)$, one can numerically verify that the conditions (27), (28) and (25) are satisfied for all $\alpha \leq \alpha_{\text{crit}} = 0.002$. Therefore, for that rate, we establish a fraction of correctable errors which is more than ten times higher than the previously known worst-case results, as claimed.

V. CONCLUSION

The main contribution of this paper is to perform probabilistic analysis of linear programming (LP) decoding of low-density parity-check (LDPC) codes in the finite-length regime. Specifically, we showed that for a random LDPC code ensemble, the linear programming decoder of Feldman et al. succeeds (with high probability) in correcting a constant fraction of errors that surpasses all prior non-asymptotic results for LDPC codes. For a rate 0.5 code, it exceeds the best previous finite-length result on LP decoding by a factor greater than ten. Despite these substantial improvement, it should be noted that our analysis still yields very conservative results, roughly a factor of 50 lower than the typical empirical performance of these codes, as well as the associated asymptotic thresholds.

Perhaps more important than specific numerical improvements over past results are the technical innovations that underlie our analysis: a direct treatment of the probabilistic nature
of bit-flipping channels (as opposed to adversarial analysis in previous work), and a novel combinatorial characterization of LP decoding, based on the notion of a poison hyperflow witness. This hyperflow perspective illustrates that the factor graph defining a good code should have good flow properties, in the sense that no matter which subset of bits are flipped, the poison associated with errors can be diffused and routed to the unflipped bits. For more general MBIOS channels, the amount of poison corresponds exactly to the negative log-likelihood that the channel is assigning to each bit, and the same characterization of LP decoding holds.

This intuition suggests that the property of supporting sufficient hyperflow could provide a useful design principle in the finite-length setting, for example small sets of variables which contract (are jointly adjacent to few checks) will cause in the finite-length setting, for example small sets of variables which contract (are jointly adjacent to few checks) will cause sufficient hyperflow could provide a useful design principle in the finite-length setting. In addition, it remains to further explore which contract (are jointly adjacent to few checks) will cause sufficient hyperflow could provide a useful design principle in the finite-length setting.

There are a number of ways in which specific technical aspects of the current analysis can likely be sharpened, which await further work. In addition, it remains to further explore the consequences of our analysis technique for other channels and code ensembles, beyond the particular LDPC ensemble and binary symmetric channel considered here.

APPENDIX

A. Proof of Proposition 7

One direction of the claim is immediate: given the weights $\tau'_{ij}$ of any hyperflow, they must satisfy condition (65) by definition, and moreover it is easy to see that condition (65) will be automatically satisfied. In the other direction, we transform the edge weights $\tau_{ij}$ to new weights $\tau'_{ij}$ that satisfy the hyperflow constraints. For each check $j$ separately, we replace the weights $\tau_{ij}$ on the adjacent edges with new weights that satisfy the hyperflow constraints and, at the same time, do not violate any of the constraints in condition (65). Consider a check $j$ and order the weights on the adjacent edges in...
increasing order. Assuming that the check has degree \(d(j)\), consider the following cases:

**Case I:** \(0 \leq \tau_{ij} \leq \tau_{ij} \cdots \leq \tau_{dj}j\). In this case, set \(\tau_{ij} = 0\) for all \(i\). The new weights are clearly hyperflow weights and, moreover, it is not hard to verify that none of the conditions \(6b\) are violated by the transformation.

**Case II:** \(\tau_{ij} \leq 0 \leq \tau_{ij} \cdots \leq \tau_{dj}j\). Set \(P_j = -\tau_{ij}, \tau_{ij} = P_j - P_j, \forall \in N(j) \setminus \{1\}\). This is a hyperflow weight assignment by construction. Observe, also, that none of the conditions \(6b\) for the variables in \(N(j)\) are violated by this transformation: indeed, for each variable \(k \in N(j)\), we have that \(\tau_{kj} \geq -\tau_{ij}\) since the weights \(\tau_{ij}\) satisfy \(6b\); therefore, setting \(\tau_{kj} = -\tau_{ij}\) only makes the sum of the edges adjacent to variable \(k\) smaller, and the sum was already satisfying condition \(6b\) before the transformation.

To conclude the claim, notice that at most one edge adjacent to every check \(j\) can have negative weight in assignment \(\tau_{ij}\); otherwise, condition \(6b\) would be violated for that check. \(\square\)

### B. Elementary bounds on binomial coefficients

For each \(\beta \in (0, 1)\), define the binomial entropy

\[
H(\beta) := -\beta \log_2 \beta - (1 - \beta) \log_2 (1 - \beta),
\]

with \(H(0) = H(1) = 0\) by continuity. We make use of standard asymptotics of binomial coefficients: for all integers \(k\) in the interval \([0, n]\), we have

\[
\frac{1}{n} \log \binom{n}{k} = H(k/n) + o(1)
\]

as \(n\) tends to infinity (e.g., see Cover and Thomas [7]).

### C. Proof of Lemma

Note that conditioned on the event \(T(\epsilon)\), we are guaranteed that \(\sum_{i=1}^q d_i Y_i \leq \bar{\gamma} n\). Letting \(S'_i\) be the fixed subset \(\{1, \ldots, s_1\}\), define the event \(E(s_1) := \{|N(S'_i)| \leq p s_1 + \bar{\gamma} n\}\) and the quantity

\[
P(s_1) := \binom{[\alpha n]}{s_1} Q[E(s_1)].
\]

Using the nature of the bit-regular random ensemble, we have

\[
P(s_1) \leq \binom{[\alpha n]}{s_1} \binom{[1 - R]n}{[p s_1 + \bar{\gamma} n]} \binom{[1 - R]n}{[1 - R]n} d_{s_1},
\]

where the probability \(1/n \log P(s_1)\) is upper bounded by

\[
\left[\alpha H\left(\frac{s_1}{\alpha}\right) + (1 - R)H\left(\frac{p s_1 + \bar{\gamma}}{1 - R}\right) + d_{s_1} s_1 \log_2\left(\frac{p s_1 + \bar{\gamma}}{1 - R}\right) + o(1)\right].
\]

Defining the function \(f\) and value \(s_{crit}\) as in the lemma statement, we are guaranteed that \(P(s_1)\) decays exponentially in \(n\) for all \(s_1 \in \{[s_{crit}n] + 1, \ldots, [\alpha n]\}\). To complete the proof of the claim, we claim that \(D(s_1)\) can be upper bounded by \(P(s_1)\). Indeed, for \(s_1 \in \{[s_{crit}n] + 1, \ldots, [\alpha n]\}\), we can either condition on \(\mathcal{E}(s_1)\) or its complement to obtain that \(D(s_1)\) is upper bounded by

\[
\left\{\binom{[\alpha n]}{s_1} Q[\exists \mathcal{E}(s_1) \in A_2 \mid \mathcal{E}(s_1) \in \mathcal{E}(s_1)] + Q[\mathcal{E}(s_1)]\right\},
\]

which is equal to \(P(s_1)\) because, as argued in Section IV-B, conditioned on the event \(\mathcal{E}(s_1)\), there can be no \(S_2\) such that the event \(B(S'_1, S_2)\) holds.

### D. Proof of Lemma

We have the bound

\[
E(\gamma_1, s_1) \leq \binom{[\alpha n]}{s_1} Q[|N(S_1)| = \gamma_1 \mid |S_1| = s_1],
\]

where we have used the fact that the event \(\{|N(S_1)| = \gamma_1\}\) is independent of \(T(\epsilon)\) under the probability distribution \(Q\). An exact computation yields that \(1/n \log Q[|N(S_1)| = \gamma_1 \mid |S_1| = s_1]\) is upper bounded by

\[
\frac{1}{n} \log \left(\frac{(1 - R)n}{\gamma_1} \frac{\gamma_1}{(1 - R)n}\right)^{d_{s_1}},
\]

which is in turn upper bounded by

\[
\ell(s_1) := (1 - R)H\left(\frac{\gamma_1}{(1 - R)n}\right) + d_{s_1} s_1 \log_2\left(\frac{\gamma_1}{(1 - R)n}\right) + o(1),
\]

where we have used standard bounds on binomial coefficients [29]. Overall, we have

\[
\frac{1}{n} \log E(\gamma_1, s_1) \leq \alpha H\left(\frac{s_1}{[\alpha n]}\right) + \ell(s_1)
\]

\[
\leq \left\{2 + d_{s_1} s_1 \log_2\left(\frac{\gamma_1}{(1 - R)n}\right)\right\},
\]

since \(\alpha, R \in (0, 1)\), and each entropy term remains bounded within \([0, 1]\).

Finally, setting \(s_1 = s_1/n\) and \(\gamma_1 = \gamma_1/n\), consider the function

\[
g(\gamma_1) := 2 + d_{s_1} s_1 \log_2\left(\frac{\gamma_1}{(1 - R)}\right).
\]

We have \(\lim_{\gamma_1 \to 0^+} g(\gamma_1) = -\infty\), implying that \(E(\gamma_1, s_1)\) decays exponentially fast in \(n\) for all \(s_1 \geq [\epsilon_2 n]\) and neighborhood sizes \(\gamma_1 \leq \gamma_{crit}(\epsilon_2) n\), where \(\gamma_{crit}(\cdot)\) is defined as in the statement of the lemma.
E. Proof of Lemma 7

We begin by proving the following lemma, which provides an upper bound on the quantity $E(\gamma_1, s_1)$.

**Lemma 9 (Upper Regime):** If the three conditions (25) hold, then, for all $s_1 \in \{\lfloor \epsilon_2 n \rfloor, \ldots, \lfloor \gamma_\text{crit} n \rfloor \}$ and $\gamma_1 \geq \gamma_\text{crit}(\epsilon_2) n$, there exists some $\gamma_* = \gamma_*^*(\xi, \epsilon_2) > 0$ such that

$$\frac{1}{n} \log E(s_1, \gamma_1) \leq \sum_{k=1}^{3} \min\{0, T_k(s_1, \gamma_1)\} + T_4(s_1, \gamma_1) + o(1),$$

where

$$T_1 = \frac{1}{n} \log \left( (1-R)n \right) \frac{\gamma_1}{\gamma_1} (\alpha n - s_1),$$

$$T_2 = \frac{1}{n} \log \left( (1-R)n \right) \frac{\gamma_2}{\gamma_1} (\alpha n - s_1),$$

$$T_3 = \frac{1}{n} \log \left( \min\{\beta(s_1, \gamma_1, y_2)\} \right) + \frac{1}{n} \log \left( \gamma_1 + \gamma_2 \right),$$

$$T_4 = \max_{\gamma_2 \in \Gamma_{y_i}, y_i} \left\{ \sum_{i=1}^{q} \frac{1}{n} \log \left( \frac{g_i^\text{up} n}{y_i} \right) \right\}$$

where

$$\Gamma : = \{\gamma_2 n, \lfloor \gamma_2 n \rfloor + 1, \ldots, d_v (\alpha n - s_1) \}$$

and

$$\gamma_i : = \left\{ \left\lfloor \frac{g_i^\text{up} n}{2} \right\rfloor, \ldots, \left\lceil \frac{g_i^\text{up} n}{2} \right\rceil \right\}, \quad \text{for } i = 1, \ldots, q.$$

**Proof:**
We begin with the decomposition

$$E(s_1, \gamma_1) = \left( \lfloor \alpha n \rfloor \right) \sum_{\gamma_2 = 1}^{\alpha n - s_1} U_1(\gamma_1, \gamma_2) U_2(\gamma_1, \gamma_2),$$

where

$$U_1(\gamma_1, \gamma_2) := \mathbb{Q}' \bigg| \prod_{S \in A_2} \Big( N(S_1) \big| = \gamma_1, \big| N(F) \setminus N(S_1) \big| = \gamma_2, \big| S_1 \big| = s_1 \bigg|, \big| N(S_1) \big| = \gamma_1, \big| S_2 \big| = s_1 \bigg),$$

$$U_2(\gamma_1, \gamma_2) := \mathbb{Q}' \bigg| \prod_{S \in A_2} \Big( N(S_1) \big| = \gamma_1, \big| N(F) \setminus N(S_1) \big| = \gamma_2, \big| S_1 \big| = s_1 \bigg),$$

and recall that $\mathbb{Q}'$ is the distribution $\mathbb{Q}$ conditioned on the event $T(\epsilon_2)$. We now require a lemma that allows us to restrict appropriately the range of summation over to values of $\gamma_2$ that scale linearly in $n$.

**Lemma 10:** ($\gamma_2$ small): The conditions of Lemma 9 imply that there exists some value $\gamma_* = \gamma_*^*(\xi, \epsilon_2) > 0$ for which the quantity

$$G(s_1, \gamma_1) := \left( \lfloor \alpha n \rfloor \right) \sum_{\gamma_2 = 1}^{\gamma_*} U_1(\gamma_1, \gamma_2) U_2(\gamma_1, \gamma_2)$$

decays exponentially in $n$ for any $s_1, \gamma_1$ that satisfy $\lfloor \epsilon_2 n \rfloor \leq s_1 \leq \lfloor \gamma_\text{crit} n \rfloor$ and $\gamma_1 \geq \gamma_\text{crit}(\epsilon_2) n$.

**Proof:** The proof is similar in spirit to the proof of Lemma 6. Taking a term in the summation (30), we can bound it as follows:

$$B(s_1, \gamma_1, \gamma_2) := \left( \left\lfloor \frac{\alpha n}{s_1} \right\rfloor \right) U_1(\gamma_1, \gamma_2) U_2(\gamma_1, \gamma_2)$$

$$\leq \left( \frac{\alpha n}{s_1} \right) U_2(\gamma_1, \gamma_2),$$

which is upper bounded by

$$\left( \frac{\alpha n}{s_1} \right) Q' \bigg| \big| N(F) \setminus N(S_1) \big| = \gamma_2 \bigg| \big| N(S_1) \big| = \gamma_1, \big| S_1 \big| = s_1 \bigg).$$

Note that $Q'$ term is upper bounded by

$$\frac{1}{n} \log_2 B(s_1, \gamma_1, \gamma_2) \leq \sum_{i=1}^{3} C_i(s_1, \gamma_1, \gamma_2) + o(1),$$

where

$$C_1 = \alpha H \left( \frac{s_1/n}{\alpha} \right),$$

$$C_2 = H \left( \frac{\gamma_2/n}{1 - R - \gamma_1/n} \right),$$

$$C_3 = d_v \left( \alpha - \frac{s_1}{n} \right) \log_2 \left( \frac{\gamma_2/n + \gamma_1/n}{1 - R} \right).$$

Using conditions (25), since $\bar{\gamma}_\text{crit} < \frac{\gamma_1}{2}$, the term $C_1$ is increasing in $s_1/n$. Moreover, since $\alpha d_v < \frac{(1-R)\bar{\gamma}_\text{crit}}{2}$, second entropy term is the term $C_2$ increasing in $\gamma_1$. Finally, the term $C_3$ increasing in $s_1/n$ and in $\gamma_1/n$. Consequently, $\frac{1}{n} \log_2 B(s_1, \gamma_1, \gamma_2)$ is upper bounded by the function

$$b(\gamma) := \alpha H \left( \frac{\bar{\gamma}_\text{crit}}{\alpha} \right) + H \left( \frac{\gamma}{1 - R - d_v \bar{\gamma}_\text{crit}} \right)$$

$$+ d_v (\alpha - \bar{\gamma}_\text{crit}) \log_2 \left( \frac{\gamma + d_v \bar{\gamma}_\text{crit}}{1 - R} \right).$$

Note that $\lim_{\gamma \to 0} b(\gamma) < 0$ follows from the third condition in the series (25). The remainder of the proof is entirely analogous to that of Lemma 6.

By Lemma 10 it suffices to provide upper bounds for the terms $B(s_1, \gamma_1, \gamma_2)$ for $s_1 \in \{\lfloor \epsilon_2 n \rfloor, \ldots, \lfloor \gamma_\text{crit} n \rfloor \}$, $\gamma_1 \geq \gamma_\text{crit}(\epsilon_2) n$ and $\gamma_2 \geq \gamma_* n$. Recall the bound (33) on $Q' \bigg| \big| N(F) \setminus N(S_1) \big| = \gamma_2 \bigg| \big| N(S_1) \big| = \gamma_1, \big| S_1 \big| = s_1 \bigg)$. Similarly, recall from Appendix G that $Q' \bigg| \big| N(S_1) \big| = \gamma_1, \big| S_1 \big| = s_1 \bigg)$ is upper bounded by

$$\left( \frac{(1-R)n}{\gamma_1} \right) \frac{\gamma_1}{((1-R)n)^d_{\gamma_1}}.$$

Recalling the notation $S_1^*$ for the fixed set $\{1, \ldots, s_1\}$, he only missing piece is an upper bound on

$$Q' \bigg| \prod_{S \in A_2} \bigg| N(S_1^*) \bigg| = \gamma_1, \big| N(F) \setminus N(S_1^*) \big| = \gamma_2 \bigg).$$
Recall that $Q'$ is the conditional probability given the event $\{T(\epsilon_1)\}$. In this space, every set $S_2 \in F^c(q)$ corresponds to a request vector $y \in \prod_{i=1}^q \{0, \ldots, \lceil \frac{y_{ip}^n}{n} \rceil\}$. Moreover, for a set $S_2 \in F^c(q)$ and its corresponding request vector $y$, the event $B(S_1^*, S_2)$ is equivalent to the following condition being satisfied:

$$B(S_1^*, S_2) \iff \left| (N(S_2) \cap N(F)) - N(S_1^*) \right| \leq \beta(s_1, \gamma_1, y).$$

Therefore, a union bound over all the possible choices of sets $S_2$ gives the following upper bound for the probability of interest:

$$\sum_{y_1=0}^{\lceil \frac{y_{1p}^n}{y_1} \rceil} \cdots \sum_{y_q=0}^{\lceil \frac{y_{qp}^n}{y_q} \rceil} \left( \left( \frac{y_{1p}^n}{y_1} \right) \cdots \left( \frac{y_{qp}^n}{y_q} \right) \right) \lambda(y_1, \ldots, y_q, \gamma_1, \gamma_2),$$

where $\lambda(y_1, y_2, \ldots, y_q, \gamma_1, \gamma_2)$ is the probability, under the distribution $Q'$, of the event

$$\left\{ \left| (N(S_2) \cap N(F)) \setminus N(S_1^*) \right| \leq \beta(s_1, \gamma_1, r) \right\},$$

where $N(S_1) = \gamma_1$, $|N(F) \setminus N(S_1^*)| = \gamma_2$, and $S_2$ corresponds to request vector $y$. In order to complete the proof, we need a final observation.

**Lemma 11:** For all $i = 1, \ldots, q$, if \{y\}_j \neq 1, \gamma_1, \gamma_2$ are fixed, then the function $\Lambda(y_1, y_2, \ldots, y_q, \gamma_1, \gamma_2)$ is increasing in the scalar variable $y_i \in \{1, 2, \ldots, \lceil \frac{y_{ip}^n}{y_1} \rceil\}$.

**Proof:** Clearly $\left( \frac{y_{ip}^n}{y_i} \right)$ is increasing for $y_i \in \{1, \ldots, \lceil \frac{y_{ip}^n}{y_1} \rceil\}$. Therefore, it is enough to establish that the probability $\lambda(y_1, \ldots, y_q, \gamma_1, \gamma_2)$ is increasing for $y_i \in \{1, 2, \ldots, \lceil \frac{y_{ip}^n}{y_1} \rceil\}$. This fact follows from the same coupling argument used in Section 5-A for a variable $j \in F^c$, the number of requests $X_j$ and the size of the intersection $|N(j) \cap N(F)|$ are positively correlated. Therefore, increasing the number of edges can only increase the probability $\lambda(y_1, \ldots, y_q, \gamma_1, \gamma_2)$ of the bad event $B(S_1, S_2)$.

Using Lemma 11 we can now conclude the proof of Lemma 9. Denote by $Y_i := \left\{ \left[ \frac{y_{ip}^n}{y_i} \right] \right\}$, we have that $\frac{1}{n} \log \prod_{i=1}^q \left[ \sum_{y_i=0}^{\lceil \frac{y_{ip}^n}{y_i} \rceil} \lambda(y_1, \ldots, y_q, \gamma_1, \gamma_2) \right]$ is upper bounded by

$$\max_{y_i \in Y_i} \left\{ \frac{1}{n} \log \left( \frac{\gamma_2}{y_i} \right) + \frac{1}{n} \log \lambda(y_1, \ldots, y_q, \gamma_1, \gamma_2) \right\}.$$

By union bound, the quantity $\frac{1}{n} \log \lambda(y_1, \ldots, y_q, \gamma_1, \gamma_2)$ is upper bounded by

$$\frac{1}{n} \log \left( \min \{\beta(s_1, \gamma_1, r), \gamma_2\} \right) \times \frac{\gamma_1 + \min \{\beta(s_1, \gamma_1, r), \gamma_2\}}{\gamma_1 + \gamma_2} \nu(r).$$

Putting everything together yields the claim of Lemma 9.

Based on the preceding analysis, we can now complete our proof of Lemma 7. Indeed, using Lemmas 5, 6, and 9 we can upper bound $\frac{1}{n} \log \mathbb{Q}[B(A_2) \mid T(\epsilon_1)]$. In this upper bound, all the relevant quantities (i.e., $s_1$, $\gamma_1$, $\gamma_2$, $y_1, y_2, \ldots, y_q$) scale linearly with $n$. Therefore, standard bounds on binomial coefficients \cite{29} lead to the claimed form of $F$.

**F. Proof of Lemma 8**

The last thing we need to do is bound the probability of the bad event $Q'[B(A_3)]$ (some fixed set of size $s_1$). As usual, we do a union bound over $S_1$ sets of various sizes contracting. Define

$$D'(s_1) = \left( \frac{\alpha n}{s_1} \right) Q'[\exists S_2 \subseteq F^c(q) \text{ with } (S_1, S_2) \in A_3 \quad \text{s.t.} \quad B(S_1, S_2) \mid S_1 \text{ is some fixed set of size } s_1] \right.$$ 

and therefore

$$Q'[B(A_3)] \leq \sum_{s_1=1}^{s_2 n} D'(s_1).$$

Intuitively, it should be clear that this is the easiest regime, because handling requests from $S_1$ is always harder compared to requests from $S_2$ (because variables in $S_2$ have fewer requests). We will make $\epsilon_2$ small enough so that the requests from $S_1$ are completely covered from the neighborhood of $S_2$ (which is always larger than a linear fraction). The function we obtain is strictly dominated by $F(\alpha)$ for sufficiently small $\epsilon_2$, as one would expect, since $F(\alpha)$ is satisfying the requests in a harder regime. We make a formal argument using continuity to establish this fact.

For $\epsilon_2$ sufficiently small, we have that, for all $s_1 \in \{1, \ldots, \lfloor \epsilon_2 n \rfloor\}$,

$$\left( \frac{\alpha n}{s_1} \right) \leq \left( \frac{\alpha n}{\epsilon_2 n} \right) \leq n \left( \alpha H \left( \frac{\epsilon_2}{\alpha} \right) + o(1) \right).$$

The remainder of the analysis exploits the fact that for $\epsilon_2$ sufficiently small and any set $S_2$ of size at least $\rho n$, if $y$ is the vector of requests from $S_2$, then, with high probability,

$$|N(S_2) \cap (N(F) \setminus N(S_1))| \geq \sum_{i=1}^q i y_i + p \epsilon_2 n. \beta(\epsilon_2, y).$$

In words, the neighborhood of set $S_2$ inside $N(F) \setminus N(S_1)$ is sufficiently large not only to cover the requests from set $S_2$ but also from $S_1$. We are going to bound the probability of failure, by only allowing $S_2$ to cover all the requests:

$$Q'[\exists S_2 \subseteq F^c(q) \text{ with } (S_1, S_2) \in A_3 \quad \text{s.t.} \quad B(S_1, S_2) \mid S_1 \text{ some fixed set of size } s_1 \leq Q'[\exists S_2 \subseteq F^c(q) \text{ with } (S_1, S_2) \in A_3 \quad \text{s.t.} \quad |N(S_2) \cap (N(F) \setminus N(S_1))| \leq \beta'(\epsilon_2, y), \quad S_1 \text{ some fixed set of size } s_1].$$
By similar analysis as in the proof of Lemma 9, we obtain

\[
\frac{1}{n} \log D'(S_1) \leq F'(\alpha, \epsilon_2) + o(1),
\]

where

\[
F'(\alpha, \epsilon_2) := \sup_{\tau_2 \in [0, d_\alpha]} \sup_{y \in [y_{1p}^{\tau_2}, y_{2p}^{\tau_2}]} G''(\tau, \bar{y}_1, \bar{y}_2, \ldots, \bar{y}_q, \epsilon_2),
\]

and the intermediate function

\[
G' = G'(\tau_2, \bar{y}_1, \ldots, \bar{y}_q, \epsilon_2) = \sum_{i=1}^2 \min \{0, G'_i(\tau_2, \bar{y})\} + G'_3(\tau_2, \bar{y})
\]

has terms

\[
G'_1 = \alpha H\left(\frac{\epsilon_2}{\alpha}\right) + \sum_{i=1}^{q} \beta_i^{\tau_2} H\left(\frac{\bar{y}_i}{\bar{y}_{1p}}\right),
\]

\[
G'_2 = \gamma_2 H\left(\frac{\min\{\tau_2, \beta(\epsilon_2, \bar{y})\}}{\beta_2}\right) + \nu(\bar{y}) \log_2 \left(\frac{d_\epsilon \epsilon_2 + \gamma_2}{(1 - R)}\right),
\]

\[
G'_3 = \gamma_2 H\left(\frac{\min\{\tau_2, \beta(\epsilon_2, \bar{y})\}}{\beta_2}\right) + \nu(\bar{y}) \log_2 \left(\frac{d_\epsilon \epsilon_2 + \gamma_2}{(1 - R)}\right).
\]

Note that

\[
\lim_{\epsilon_2 \to 0} G'(\tau_2, \bar{y}_1, \ldots, \bar{y}_q, \epsilon_2) = \lim_{\alpha \to 0, \gamma_1 \to 0} G(\tau_1, \tau_2, \bar{y}_1, \ldots, \bar{y}_q, \epsilon_2),
\]

where the limit is taken by setting \(\gamma_1 = \Theta(\tau_1)\) (which will be true by concentration). Therefore, we have

\[
\lim_{\epsilon_2 \to 0} F'(\alpha, \epsilon_2) \leq F(\alpha).
\]

Consequently, if \(F(\alpha) < 0\), it then follows that

\[
\lim_{\epsilon_2 \to 0} F'(\alpha, \epsilon_2) < 0.
\]

By continuity, there exists some value \(\epsilon_2 > 0\) such that \(F'(\alpha, \epsilon_2) < 0\); for this value of \(\epsilon_2\), the probability \(\mathbb{Q}[B(A_3) \mid T(\epsilon_1)]\) decreases exponentially in \(n\).
