Received 2017 January 16; accepted 2017 March 23

Abstract The recent discoveries of pulsed X-ray emission from three ultraluminous X-ray (ULX) sources have finally enabled us to recognize a subclass within the ULX class: the great pretenders, neutron stars (NSs) that appear to emit X-ray radiation at isotropic luminosities \(L_X \approx 7 \times 10^{39} \text{ erg s}^{-1} - 1 \times 10^{41} \text{ erg s}^{-1}\) only because their emissions are strongly beamed toward our direction and our sight lines are offset by only a few degrees from their magnetic-dipole axes. The three known pretenders appear to be stronger emitters than the presumed black holes of the ULX class, such as Holmberg II & IX X-1, IC10 X-1 and NGC 300 X-1. For these three NSs, we have adopted a single reasonable assumption, that their brightest observed outbursts unfold at the Eddington rate, and we have calculated both their propeller states and their surface magnetic-field magnitudes. We find that the results are not at all different from those recently obtained for the Magellanic Be/X-ray pulsars: the three NSs reveal modest magnetic fields of about 0.3–0.4 TG and beamed propeller-line X-ray luminosities of \(\sim 10^{36} - 10^{37} \text{ erg s}^{-1}\), substantially below the Eddington limit.

Key words: accretion, accretion disks — stars: magnetic fields — stars: neutron — X-rays: binaries — X-rays: individual (M82 X-2, NGC 7793 P13, NGC 5907 ULX-1)

1 INTRODUCTION

Ultraluminous X-ray (ULX) sources are extragalactic compact accreting objects characterized by apparent super-Eddington luminosities \(L_X \approx 10^{39} - 10^{41} \text{ erg s}^{-1}\) and unusual soft X-ray spectra with blackbody (BB) emission around \(\lesssim 0.3 \text{ keV}\) and a downturn above \(\sim 3-5 \text{ keV}\) (Gladstone et al. 2009; Feng & Soria 2011; Motch et al. 2014; Middleton et al. 2015). The extreme luminosities observed during outbursts could be understood either as isotropic emission below the Eddington limit \((L_X < L_{\text{Edd}} = 1.26 \times 10^{38} \text{ } M/M_\odot \text{ erg s}^{-1})\) from intermediate-mass \((M \sim 10^{2-4} M_\odot)\) black holes (BHs) or as anisotropic emission with apparent \(L_X > L_{\text{Edd}}\) from stellar-mass BHs and neutron stars (NSs) (Soria 2007; Medvedev & Poutanen 2013; Bachetti et al. 2014; Motch et al. 2014; Pasham et al. 2014).

The former interpretation was not supported by the results of Gladstone et al. (2009) and it is now effectively ruled out by a large number of observations:

(a) Gilfanov et al. (2004) found that the ULX sources are just the high end of a luminosity function that cuts off at \(L_X \sim 3 \times 10^{40} \text{ erg s}^{-1}\) and in which the
known high-mass X-ray binaries (HMXBs) make up the low end of a single power-law with slope \( \sim 1.6 \).

(b) Liu et al. (2013) determined from optical spectroscopy that the mass of the compact object in M101 ULX-1 is no more than 30 \( M_\odot \). It is unlikely that this is an intermediate-mass BH.

(c) Luangtip et al. (2014) analyzed a Chandra sample of nearby ULX sources and found a change in the spectral index around \( L_X \sim 2 \times 10^{39} \text{ erg s}^{-1} \) that may indicate a transition to the apparent super-Eddington accretion regime by 10 \( M_\odot \) BHs or to strongly anisotropic emission from NSs. This result was confirmed by the independent study of Sutton et al. (2017).

(d) Bachetti et al. (2014) determined that the ULX source X-2 in M82 harbors a pulsar with spin period \( P_S = 1.3725 \text{ s} \) and spinup rate \( \dot{P}_S = -2 \times 10^{-10} \text{ s s}^{-1} \).

(e) Motch et al. (2014) determined that the ULX source P13 in NGC 7793 harbors a stellar-mass compact object with \( M < 15 \, M_\odot \). Pulsations were next detected from this source (Fürst et al. 2016; Israel et al. 2017b), so now we know that the compact object is an NS with \( P_S = 0.417 \text{ s} \) and an average \( \dot{P}_S = -3.5 \times 10^{-11} \text{ s s}^{-1} \).

(f) Laycock et al. (2015) determined from the radial velocity curve of IC10 X-1 that the compact object could be an NS, although a low-stellar-mass BH cannot be ruled out.

(g) Israel et al. (2017a) detected pulsations from NGC 5907 ULX-1, so this is the third object of the class harboring an NS with \( P_S = 1.137 \text{ s} \) and an average \( \dot{P}_S = -8.1 \times 10^{-10} \text{ s s}^{-1} \). This is also the most luminous and the most distant NS pretender ever detected, given its apparent luminosity of \( L_X = 10^{41} \text{ erg s}^{-1} \) and a distance to the source of \( D = 17.1 \text{ Mpc} \).

The magnetic field of NGC 7793 P13 has been recently estimated to be \( B \approx 1.5 \text{ TG} \) (Fürst et al. 2016), and in the case of M82 X-2, Bachetti et al. (2014) used their measurement of the accretion torque to obtain a modest value of the magnetic field \( B \approx 1 \text{ TG} \). Somewhat higher values were obtained by Israel et al. (2017a) for the magnetic field of NGC 5907 ULX-1 in which these authors also analyzed the possibility of multipolar fields on the surface of the NS (see also Chen 2017, for a similar analysis in the case of M82 X-2). As we shall see below, such assumptions may not be necessary as the faint X-ray states and the magnetic fields of these NSs are determined to be quite modest and in strong agreement with the estimates of King & Lasota (2016) for M82 X-2 and with the estimates of Christodoulou et al. (2016) for several Magellanic HMXBs.

More evidence keeps piling up that the magnetic fields of the ULX objects are not exotic. For instance, Brightman et al. (2016), based on NuSTAR observations of M82 X-2, found a spectral cutoff at \( 14^{+5}_{-3} \text{ keV} \) which implies a 1.2 TG surface magnetic field. On the other hand, Tsygankov et al. (2016) and Dall’Osso et al. (2016) have interpreted the faintest states of M82 X-2 as low-level emission that occurs due to leakage and continued accretion of matter when the system moves into the Corbet (1996) gap. As we shall see below, this interpretation that leads to higher magnetic-field values is not supported by the theory or observations of the other two pretenders.

In Section 2, we calculate the physical properties of the faintest accreting states of the three NS pretenders (their so-called “propeller” states) that lie at anisotropic X-ray luminosities of \( \sim 10^{36} - 10^{37} \text{ erg s}^{-1} \). We adopt a single reasonable assumption, that the brightest radiation seen from these NSs is beamed emission that proceeds at the Eddington rate\(^1\) (despite the observed spread of more than an order of magnitude in the highest X-ray luminosities of these sources). In that respect, the outbursts of these sources are not at all dissimilar from the type-II outbursts of Magellanic Be/X-ray pulsars that have been observed to rise up to the Eddington limit (Coe et al. 2010; Christodoulou et al. 2016, their figs. 2 and 4). Then we show that at their faintest accreting states, these objects appear to be very similar and typical NSs; emitting anisotropically modest amounts of radiation; and supporting modest surface magnetic fields; properties that are quite similar to those also found for the propeller emission states of the Magellanic Be/X-ray pulsars. In Section 3, we discuss and summarize our results.

## 2 THE PROPELLER STATES OF THE THREE PRETENDERS

In Table 1, we summarize the recent measurements of properties of the three NS pretenders. Two trends appear to be common for the group:

1. The NSs are spinning up over times that span 18 days (M82 X-2) to 4–12 years (12 years in the case of NGC 5907 ULX-1; Israel et al. 2017a). This indicates that accretion of matter with high specific angular momentum spins up these pulsars while, at the same time, changes in the magnetospheres (such as

\(^1\) This assumption is supported by the recent simulations of anisotropic outflows from NS accretion columns by Kawashima et al. (2016).
the opening of magnetic-field lines and electric currents flowing along open lines) are not able to generate strong enough retarding torques\(^2\) to reverse this secular trend (Harding et al. 1999; Contopoulos et al. 1999, 2014).

(2) The lowest observed X-ray luminosities \(L_{\text{min}}\) are deceptively close to the Eddington limit for the canonical \(1.4 \, M_\odot\) pulsar. But we cannot trust this trend to be more than a coincidence because we do not know whether these \(L_{\text{min}}\) values represent faint accreting states or faint magnetospheric emission (Campana et al. 1995; Campana 1997), since pulsations have not been detected in these observations. The nature of these states can be revealed after the nature of the brightest states \(L_{\text{max}}\) is deciphered (see below).

\(^2\) Using eq. (18) in Contopoulos et al. (2014), the measured values of \(P_S\), and the below-determined values of \(B\), we find that the spin-down rates for the pretenders are \(P_{SD} = 0.82\pi^2 B^2 R^6/(c^6 P_S^3) \sim 10^{-17} \text{s}^{-1}\), values that are clearly negligible as compared to the measured spin-up rates listed in Table 1. Here \(c\) is the speed of light and \(R\) and \(I\) are the canonical values of the NS radius and moment of inertia, respectively. For pulsars such as the pretenders with \(P_S \sim 1 \text{s}\), this estimate can be increased by a factor of \((R_{\text{cy}}/R_{\odot})^2 \sim 10^5\) depending on the locations of the corotation radius \(R_{\odot}\) and the light-cylinder radius \(R_{\text{cy}}\) (Contopoulos 2005), but still the resulting spin-down rates are orders of magnitude smaller than the observed spin-up rates. It appears then that in pulsars with \(P_S \sim 1 \text{s}\), the inward push of the accretion disks cannot disrupt the magnetospheres enough to affect strong electromagnetic spin-down.

We carry out a sequence of calculations that we also summarize in the rows of Table 2. We begin with the extreme values of the observed X-ray luminosities \(L_{\text{max}}\) (Table 1) which we introduce in the first row of Table 2. As many other researchers have stated in the past, we believe that these luminosities cannot indicate isotropic emissions from these pulsars—instead, the radiation must be strongly beamed toward our direction. But we do realize that the sources displaying these \(L_{\text{max}}\) values are undergoing powerful collimated outbursts, in which case it is reasonable to assume that the emitted radiation is limited by the Eddington rate in all cases (see also footnote 1). We also adopt canonical pulsar parameters (mass \(M = 1.4 \, M_\odot\) and radius \(R = 10 \text{ km}\) throughout the derivations. Then \(L_{\text{Edd}} = 1.8 \times 10^{38} \text{ erg s}^{-1}\), and we can calculate the beaming factors of the emitted X-rays which we define here as

\[
\frac{L_{\text{max}}}{L_{\text{Edd}}} > 1. \quad (1)
\]

The beaming factors for critical accretion give us an idea about the half-opening angles \(\theta_\perp\) of the collimated emissions. The solid angles are \(4\pi/b\) steradians and then the
half-opening angles of the emission cones $\theta_{\Delta}$ are given by $\pi(\theta_{\Delta})^2 = 4\pi/b$, viz.

\[ \theta_{\Delta} = \left( \frac{360}{\pi} \right) b^{-1/2} \text{deg.} \]  

(2)

We find that $\theta_{\Delta}$ varies between $5^\circ$ and $18^\circ$, where the most stringent value corresponds to the most luminous outburst (NGC 5907 ULX-1 in Table 2). This value is in agreement with the range of $\alpha_{\Delta} = 5.0^\circ - 6.7^\circ$ found for this source by Dauser et al. (2017) who produced a model with a slightly precessing inflow and outflow and strong beaming. The accretion in this model is however supercritical and the maximum anisotropic luminosity emitted in the funnel is found to be in the range of $(5–8)$ $L_{\text{Edd}}$. Nevertheless, the model of Dauser et al. (2017) is important because it shows that a slight precession of the outflow can reproduce the nearly sinusoidal pulse profiles observed in the NS pretenders. The shape of the pulse profiles was used in the past to raise objections against strong beaming (Bachetti et al. 2014; Brightman et al. 2016; Fürst et al. 2016, among others), but now it does not appear to be a problem.

Next we use the measured values of $P_S$ and $\dot{P_S}$ (Table 1) to find the isotropic X-ray luminosities $L_{\text{iso}}$ of the NSs in their faintest accreting states (Appendix B in Galache et al. 2008; Frank et al. 2002), viz.

\[ L_{\text{iso}} = \frac{1}{2} \eta \left( 2\pi I |\dot{P_S}| \right) \left( \frac{2\pi GM}{P_S^2 R^3} \right )^{1/3}, \]  

(3)

where $I$ is the canonical moment of inertia, $G$ is the gravitational constant, and we introduced an additional factor of $\eta/2$ for the efficiency of converting accretion power to X-rays ($\eta$ taken here to be 0.5). The leading factor of $1/2$ applies specifically to collimated outflows from NSs (Körding et al. 2006) and it implies an effective NS conversion efficiency of $\eta/2 = 0.25$. The introduction of $\eta/2$ also implies that we assume that minimum accretion takes place at a reduced torque compared to the observed maximum value. In the case of M82 X-2, this is certainly true because the observed value of $\dot{P_S}$ was obtained only at outburst and for a very limited time span of 18 days (fig. 2a in Bachetti et al. 2014).

Next the isotropic “propeller” luminosities $L_{\text{iso}}$ are scaled by $b$ and the true anisotropic X-ray luminosities

\[ L_{\text{prop}} = \frac{L_{\text{iso}}}{b}, \]  

(4)

are obtained for collimated emission in the propeller states (see Table 2). The faintest observed isotropic luminosities $L_{\text{min}}$ shown in Table 1 are also scaled by $b$ and they are introduced at the bottom of Table 2 for comparison purposes.

Finally, a minimum value for the surface magnetic field $B$ is estimated from the standard equation of Stella et al. (1986) for the propeller line, viz.

\[ L_{\text{prop}} = 2 \times 10^{37} \left( \frac{\mu}{10^{30} \text{G cm}^3} \right )^2 \left( \frac{P_S}{1\text{s}} \right )^{-7/3} \]  

\[ \text{erg s}^{-1}, \]  

(5)

where canonical pulsar parameters have been used and the magnetic moment is defined by

\[ \mu \equiv BR^3. \]  

(6)

This equation does not depend on $P_S$, thus it does not rely on torque balance at the inner edge of the accretion disk and it does not use conservation of angular momentum (Frank et al. 2002) in determination of the magnetic field.

The results for $L_{\text{prop}}$ summarized in Table 2 are plotted in the $P_S - L_X$ diagram in Figure 1 as filled circles. We see now that these three pulsars are totally nonexotic, sporting propeller luminosities in the range of $L_{\text{prop}} \sim 10^{36} - 10^{37}$ erg s$^{-1}$ and surface magnetic fields in the range of $B \approx 0.3 - 0.4$ TG. In these respects, the pretenders are not at all dissimilar from the short-period HMXBs found in the Magellanic Clouds and studied under the assumption of isotropic emission (Christodoulou et al. 2016). In fact, several of the Magellanic sources also appear to rise up during powerful type-II outbursts to just about the Eddington limit, an observation that is responsible for our adoption of this assumption in the present work.

The $B$-values found for the three pretenders are in agreement with the results obtained by King & Lasota (2016) for M82 X-2 and other accreting NSs that exhibit beamed emission at the apparent level of $L_{\text{max}} \sim 10^{40}$ erg s$^{-1}$. The importance of our results is that they predict similar modest values and properties for NS ULX sources that appear to radiate at a much higher level of power (see NGC 5907 ULX-1 in Table 2).

The faintest anisotropic states $L_{\text{min}}/b$ of the three pretenders shown in Table 2 are also plotted in Figure 1 as open circles. For the measured spin periods, these states fall within the Corbet (1996) gap which suggests that we have observed weak magnetospheric emission in the absence of accretion (Campana et al. 1995; Campana 1997). The case for NGC 7793 P13 is especially strong: the faintest observation (Motch et al. 2014) lies one order of magnitude below the propeller value of $L_{\text{prop}} = 1.3 \times 10^{37}$ erg s$^{-1}$. On the other hand, the faintest observation of M82 X-2 (Brightman et al. 2016) lies only a factor of $\sim 2$ below the propeller value $L_{\text{prop}} = 1.6 \times 10^{36}$ erg s$^{-1}$. But for this pulsar there
Fig. 1 The anisotropic propeller states (i.e., the faintest accreting states; solid circles) and the faintest anisotropic states observed (open circles) in $P_S - L_X$ space for the three NS pretenders. The data points come from Tables 1 and 2. Errors are given in Table 2; error bars are very small for $P_S$ and about the size of the circles for $L_X$ (smaller for NGC 7793 P13). The dashed line is the lowest propeller line with $B = 0.3$ TG found for the Magellanic Be/X-ray pulsars (Christodoulou et al. 2016). Comparison indicates that the surface magnetic fields of these NSs are modest ($B \approx 0.3 - 0.4$ TG). The dash-dotted line with a slope of $-3$ specifies the lower boundary of the Corbet (1996) gap for the $B = 0.3$ TG propeller line.

exists an independent confirmation of its propeller value: From 15 years of Chandra observations, Tsygankov et al. (2016) found that M82 X-2 has repeatedly switched between its high isotropic state $L_{\text{max}}$ and a low isotropic state with $L_{\text{iso}} = 1.7 \times 10^{38}$ erg s$^{-1}$ (see also Dall’Osso et al. 2016, who obtained the same value as an upper limit). Using $b = 111$ (Table 2), this faint state corresponds to $L_{\text{prop}} = 1.5 \times 10^{36}$ erg s$^{-1}$ in strong agreement with our determination of the propeller value derived from beaming of the $L_{\text{max}}$ value of this source. It seems then that M82 X-2 has bounced for many years between its propeller state and its ultraluminous state. This agreement between results consolidates the physical properties of M82 X-2 listed in Table 2.

3 SUMMARY AND DISCUSSION

We have used standard accretion theory and beaming of the X-ray emission (Stella et al. 1986; Frank et al. 2002; Galache et al. 2008; King & Lasota 2016) in order to estimate the typical values of minimum anisotropic luminosities and surface magnetic fields of the three recently discovered ULX pulsars (Table 1; Bachetti et al. 2014; Fürst et al. 2016; Israel et al. 2017a,b). For the measured values of $L_{\text{max}}$, $P_S$ and $\dot{P}_S$, our results show that the physical and geometric parameters are all modest (Table 2) and not at all dissimilar (Fig. 1) from those found for the entire sample of the short-period ($P_S < 100$ s) Magellanic HMXBs (Christodoulou et al. 2016). The three modest NSs only pretend to emit at enormous super-Eddington rates because their emissions are collimated and our sight lines are close to their magnetic-dipole axes (Section 2).

Since the X-rays originate from a limited region around the magnetic poles, we can estimate the sizes $r$ and temperatures $T$ of these hot spots during the faintest accretion states in which the corotation radius is comparable to the magnetospheric radius. The radii of the hot spots are approximately given by $r = R_*/\sqrt{R_*/R_{\text{co}}}$, where $R_{\text{co}}$ is the corotation radius; and then the temperatures are $T = [L_{\text{Edd}}/(\sigma \pi r^2)]^{1/4}$, where $\sigma$ is the Stefan-Boltzmann constant. Using the values listed in Table 1, we find that typically $r = 1.0 - 0.7 \text{ km}$ and $T = (1.0 - 1.2) \times 10^8 \text{ K}$, corresponding to photon energies of $kT = 8.5 - 10.4 \text{ keV}$ at the bases of the outflows. Such temperatures may be sufficient for the production of particle pairs that can cross magnetic-field lines and escape along the magnetic axes in mildly relativistic out-
flows that help increase the effective opening angles of
the emission cones listed in Table 2.

Furthermore, if the emissions from the pretenders
are collimated, some of the energy must emerge at much
longer wavelengths. This appears to be the case for M82
X-2 according to the radio observations of Kronberg
et al. (1985), McDonald et al. (2002) and Fenech et al.
(2008), and the infrared observations of Kong et al.
(2007) and Gandhi et al. (2011). The radio maps show
a core-dominated source which is expected if the pul-

cation within such wide emission cones account for the
longer wavelengths. This appears to be the case for M82
the emission cones listed in Table 2.

In the Magellanic Clouds, two HMXBs have been
observed each during two major type-II outbursts3 with
apparent $L_{\text{max}} > L_{\text{Edd}}$; LXP8.04 (Edge et al. 2004;
Vasilopoulos et al. 2014; Tendulkar et al. 2014) and SMC
X-2 (Laycock et al. 2005; Kennea et al. 2015). As sum-
morized by Christodoulou et al. (2016), the brightest
bursts reached luminosities of $L_{\text{max}} = 8 \times 10^{38} \text{erg s}^{-1}$
(LXP8.04, $D = 50 \text{kpc}$) and $L_{\text{max}} = 4 \times 10^{38} \text{erg s}^{-1}$
(SMC X-2, $D = 60 \text{kpc}$) that reveal small beaming fac-
tors (Eq. [1]) of about 2.2 and 4.4, respectively. These
very small degrees of beaming (half-opening angles of
$\theta_2 = 77^\circ$ and $54^\circ$, respectively; Eq. [2]) and our orien-
tation within such wide emission cones account for the
differences in light curves and spectral features between
these most extreme HMXBs and the strongly beaming
NS pretenders. The ULX spectral features are discussed
below.

The main properties of the so-called ultraluminous
state (Gladelstone et al. 2009; Feng & Soria 2011; Motch
et al. 2014; Middleton et al. 2015; Kobayashi et al. 2017;
Kaaret et al. 2017) are:

1. A soft BB excess at $\lesssim 0.3 \text{ keV}$. It is believed that this
could be emission from the accretion disk.

2. A downturn of the spectrum at $\sim 3 - 5 \text{ keV}$. This is
consistent with our calculation of photon energies of
$kT = 8.5 - 10.4 \text{ keV}$ at the bases of the outflows.
Operating at $L_{\text{max}}/b = L_{\text{Edd}}$, the sources would not
be able to produce more energetic photons in sub-
stantial numbers. A large number of photons is also
able to produce emission from the sides of the accretion
column (Kawashima et al. 2016; Basko & Sunyaev
1976) in a fan-like configuration and most of them do
not reach the observer if our sight lines are oriented
close to the magnetic-dipole axes, as in the case of the
pretenders.

3. Featureless spectra with no emission/absorption
lines. This implies that the X-rays are not repro-
cessed in the surrounding medium, that is they find
holes in a clumpy medium to shine through (as was
found by Kobayashi et al. 2017, in Suzaku observations of
Holmberg IX X-1).

4. A power law at the hard part of the spectrum.
Comptonization of the primary (unprocessed) pho-
ons from the source may be responsible for this
component.

5. The soft part is often fitted well by two-color disk BB
models. Multi-color BB models could be revealing
the spectrum of a cooler wind outflow emanating in
the emission funnel (see also Walton et al. 2016).

6. No cyclotron resonance features. This can be ex-
plained by the weak magnetic fields of the pre-
tenders. For the determined values of $B = 0.3 - 0.4 \text{ TG}$, such lines may only emerge at $3.5 - 4.6 \text{ keV}$
which is the area of the spectrum downturn.

Urquhart & Soria (2016) observed eclipses in two
ULX sources in M51. For these sources, $L_{\text{max}} \approx 2 \times 10^{39} \text{ erg s}^{-1}$, substantially lower than the $L_{\text{max}}$
values of the pretenders and slightly below the empirical critical
value of $L_{\text{crit}} \sim 3 \times 10^{39} \text{ erg s}^{-1}$ (Luangtip et al.
2014; Sutton et al. 2017) that apparently subdivides the
central engines of the ULX sources into stellar-mass BHs
and NS pretenders. Since our line of sight is very much inclined
to the magnetic axes of both of these eclipsing
binaries, the radiation cannot be beamed at all. We
conclude that both of these sources contain stellar-mass
BHs with masses $M_{\text{BH}} \gtrsim 16 M_{\odot}$ radiating isotropically
at about the Eddington rate ($L_{\text{max}} \lesssim L_{\text{Edd}}$). Objects
such as these reinforce our belief that the NSs of the
ULX class only pretend to radiate more power than the
BHs of the class. In this respect, weaker sources with
$L_{\text{max}} \sim 2 \times 10^{38} \text{ erg s}^{-1}$, such as IC10 X-1 (Laycock
et al. 2015) and NGC 300 X-1 (Binder et al. 2011), that

---

3 A type-II outburst of SMC X-3 was recently reported by Weng
et al. (2017) and Tsygankov et al. (2017) and it was monitored by
Swift/XRT and NuSTAR. For this HMXB, the observations indicate
that $L_{\text{max}} = 2.5 \times 10^{39} \text{ erg s}^{-1}$ and $L_{\text{min}} = 3.0 \times 10^{38} \text{ erg s}^{-1}$
($D = 62 \text{kpc}$; Tsygankov et al. 2017). Assuming that this event was
due to critical accretion at the Eddington rate, we find that we need
modest beaming ($b = 14$ and $\theta_2 = 31^\circ$), the minimum beamed lu-
minosity $L_{\text{min}}/b$ falls in the middle of the Corbet gap, and the dipolar
magnetic field on the surface of the NS is $B = 1.1 \text{ TG}$. 
bridge the gap between HMXBs and ULX sources may not contain BHs (their masses would have to be no more than \(2 \, M_\odot\)), so they could also contain NSs; otherwise most of the radiation is beamed away from our direction (IC10 X-1 is an eclipsing binary); or accretion is markedly suppressed in these objects, perhaps for some of the reasons recently put forth by Tutukov & Fedorova (2016).

Acknowledgements We thank an anonymous referee for suggestions that led to improvements and clarifications in the paper. DMC, SGTL and RC were supported by NASA grant NNX14-AF77G. DK was supported by a NASA ADAP grant.
