(Dated: March 23, 2022)

The mobility of surface electrons localized over helium films underlying solid substrates has been evaluated by solving the Boltzmann equation in the time relaxation approximation and the force balance equation in which an effective mobility is obtained in terms of the dynamical structure factor of the nondegenerate electron liquid. The essential processes of electron scattering by gas atoms, ripplons, and film-solid interface roughness are taken into account. The electron mobility dependence on the film thickness and temperature is determined and compared with experimental data available. We find that the interface-roughness scattering is the dominant process for explaining the experimental results. We estimate the extended defect sizes of the underlying substrate within the Gaussian correlated model for interface roughness.

I. INTRODUCTION

Surface electrons (SE) levitating over liquid helium has been used as a paradigmatic quasi-two dimensional electron system (Q2DES). It constitutes the counterpart of the electron system on semiconductor heterostructures in the sense that the electrons on helium obey the classical statistics because the low densities achievable in experiments ($\lesssim 10^9$ cm$^{-2}$). One point difference between them comes from the scattering mechanisms. In the former system, electrons are scattered by surface excitations, the ripplons, and by vapor atoms of the helium surface. In the latter one, scattering by impurities, phonons, and interface roughness are the processes that limit the electron mobility. Besides the remarkable phenomena discovered in this low-dimensional electron system, for instance, Wigner crystallization and the existence of edgemagnetoplasmons,2,3 SE have been used as a probe to investigate the elementary surface excitations of cryogenic liquids and solids. Very recently there is an intensive search for experimental realization of SE as qubits leading to a quantum computer.4,5,6 For a overview of the field see Ref. 5.

For electrons trapped on the bulk helium surface it is well known that the SE mobility is dominated by the electron-helium gas atom scattering for $T > 1$ K whereas the SE scattering by quantized capillary waves (riplons) is responsible for mobility at lower temperatures where the helium vapor density becomes negligible. The experimental data for SE mobility over bulk helium are in reasonable agreement with theoretical calculations.

The situation changes when SE are floating over a helium film which in turn is deposited over a solid substrate. In such a condition it is possible to increase significantly the accessible range of electron densities and the electron correlations may become important. Furthermore, the electron energy spectrum, the ripplon dispersion relation and the electron-ripllon interaction are modified significantly due to film effects and the van der Waals forces from the substrate now play a decisive role in the transport properties. Furthermore, besides the usual scattering mechanisms pointed out above, we must consider the SE scattering by interface defects at the helium film - substrate boundary, which, as it have been shown in experiments is responsible by the unusual behavior of the SE transport properties on a helium film.10,11,12,13,14

The present work intends to provide a detailed theoretical study of the mobility of SE localized over a helium film deposited on substrates, as solid neon, glass and poly(methyl-methacrylate) [pmma], which are the materials that have been used in the experiments. We employ the Boltzmann transport equation approach (BEA) and the force balance equation method (FBEM) in which Coulomb effects on the mobility are taken into account through the dynamical structural factor of the Q2DES. We calculate the SE mobility as a function of temperature and the film thickness in the range 100 $< d < 1000$ Å. From the comparison with experimental results we check the role of all scattering processes involved and verify the reliability of the interface roughness model used in our treatment. We find that the SE mobility is strongly determined by the interface roughness substrate and the results are in quite good agreement with the experiments.

II. BASIC RELATIONS

A. Surface electron states

Electron states on a liquid helium film are confined in the direction normal to the surface (z) due to the potential well created by a infinitely high barrier which prevents the electrons penetrate inside the liquid phase and by and attractive potential due to the electron interaction with the polarizable substrates and an applied holding electric field $E_\perp$ along the z direction. The electron po-
potential energy over flat helium film located at \(-d < z < 0\) is well known and given by

\[ U(z) = -\frac{\Lambda_0}{z} - \frac{\Lambda_1}{z+d} + eE_{\perp} \]

where \(\Lambda_0 = e^2(\varepsilon_{\text{He}} - 1)/4(\varepsilon_{\text{He}} + 1)\) and \(\Lambda_1 = e^2\varepsilon_{\text{He}}(\varepsilon_s - \varepsilon_{\text{He}})(\varepsilon_{\text{He}} + 1)^2(\varepsilon_s + \varepsilon_{\text{He}})\) with \(\varepsilon_{\text{He}}\) and \(\varepsilon_s\) being the dielectric constants of helium and solid substrate, respectively, and \(e\) the electron charge.

For electrons moving freely along the helium surface with the wave function and the energy spectrum given respectively by \(\psi_i(r, z) = A^{-1/2} \exp(i\mathbf{k} \cdot \mathbf{r})\chi_i(z)\) and \(E_i(k) = \hbar^2 k^2/2m + \Delta_i\), where \(\mathbf{k}\) and \(\mathbf{r}\) are the wave vector and position vector in the plane \((x, y)\) of the liquid interface and \(A\) is surface area occupied by electrons. Unfortunately an analytical solution of Schrödinger equation for \(\chi_i(z)\) and subbands energies \(\Delta_i\) cannot be found for \(U(z)\) given by Eq. (1). In this work, we use the variational method by choosing the trial wave function \(\hat{\psi}_i(z)\) given by Eq. (1). In this work, we use the

\[ \hat{H}_{\text{er}}(\mathbf{r}) = \frac{1}{\sqrt{A}} \sum_{\mathbf{q}} \xi_1(\mathbf{q}) V_{\text{r}}(\mathbf{q}) \mathbf{a}^\dagger \mathbf{r}^\mathbf{q} \mathbf{a}^\mathbf{r}, \]

with \(\xi_1 = \frac{\Lambda_0 q^2}{z} - K_1(qz) + \frac{\Lambda_1}{(z+d)} + eE_{\perp}\)

and

\[ V_{\text{r}}(\mathbf{q}) = -\frac{\Lambda_1}{qz} \left\{ \left( \frac{2\varepsilon_{\text{He}}}{\varepsilon_s + \varepsilon_{\text{He}}} \right) \frac{qK_1[q(z+d)]}{(z+d)} + \left( \frac{\varepsilon_s - \varepsilon_{\text{He}}}{\varepsilon_s + \varepsilon_{\text{He}}} \right) \frac{q^2 K_2[q(z+d)]}{2} \right\}, \]

where \(K_j(x)\) is the modified Bessel function. Here we used the Fourier transform \(\xi_1(\mathbf{q}) = A^{-1/2} \sum_{\mathbf{q}} \xi_1(\mathbf{q}) \mathbf{a}^\dagger \mathbf{r}^\mathbf{q} \mathbf{a}^\mathbf{r}\) for \(\xi_1(\mathbf{q})\) and \(\xi_2(\mathbf{q})\) and, quantizing the oscillations of free helium surface, one obtains

\[ \xi_1(\mathbf{q}) = \sqrt{\frac{\hbar q \tanh(qd)}{2\rho \omega_q}} \left( a_q + a^\dagger_{-q} \right) \]

with \(a_q^\dagger\) and \(a_q\) being the annihilation and creation operators for ripples with wave number \(\mathbf{q}\) and satisfying the dispersion law

\[ \omega^2_q = \left( \frac{\alpha q^3 + g'q}{\rho} \right) \tanh qd, \]

where \(\alpha\) is the surface tension coefficient and \(\rho\) is the density of helium. In Eq. (4), \(g' = g + 3\beta/\rho d^3\), with \(g\) being the gravity acceleration and \(\beta\) the van der Waals constant.

Even though one cannot find from first principles the interface roughness displacement \(\xi_2(\mathbf{q})\), we will use a reasonable model to calculate the electron scattering contribution to SE transport properties.

### III. TRANSPORT PROPERTIES

#### A. Boltzmann kinetic approach

In order to calculate SE mobility along the helium surface in the presence of a driving electric field \(\mathbf{E}_{\parallel}\) we apply the well-known kinetic formalism where the electron scattering plays a crucial role in transport properties and does contribute to collision integrals in the Boltzmann equation as follows

\[ \frac{e\mathbf{E}_{\parallel}}{h} \frac{\partial f}{\partial k} = \hat{S}_{\text{rg}} \{ f \} + \hat{S}_{\text{er}} \{ f \} + \hat{S}_{\text{ei}} \{ f \}, \]

where \(f(k)\) is the electron distribution function and \(\hat{S}_{\text{rg}} \{ f \}, \hat{S}_{\text{er}} \{ f \}, \text{and} \hat{S}_{\text{ei}} \{ f \}\) are collision integrals of
electron with helium atoms, ripplons and roughness interface between the film and the substrate, respectively. By considering quasielastic scattering processes the solution of Eq. (7) is \( f(k) \approx f(0)(k) + f'(k) \cos \varphi \) where \( f(0)(k) \) is equilibrium distribution given by the Boltzmann function for the nondegenerate Q2DES, \( \varphi \) is the angle between \( k \) and \( \mathbf{E}_\parallel \), and

\[
f'(k) = -\frac{e E_\parallel}{\hbar v(k)} \frac{\partial f(0)(k)}{\partial k},
\]

where the collision frequency \( \nu(k) = \nu_{eg}(k) + \nu_{er}(k) + \nu_{ei}(k) \) and

\[
\nu_j(k) = \sum_{k'} W_j(k', k) \left( \frac{1 - f_0(k')}{1 - f_0(k)} \right) \left( 1 - \frac{k', k}{k^2} \right).
\]

The probability amplitude per unit-time \( W_j(k, k') \) for electron transition from states \( k \) to \( k' \) is given by Fermi’s golden rule and the subscript \( j \) corresponds to each scattering mechanism whose interaction potential is given by Eqs. (2) and (3). The SE mobility is then given by

\[
\mu = \frac{e}{m} \int_0^\infty \frac{x e^{-x^2 dx}}{\nu(k_T x^{1/2})} \cdot (8)
\]

where \( x = k^2/k_T^2 \), with the thermal wave vector \( k_T = \sqrt{2mT/\hbar} \).

The frequency of electron-atom collisions has been calculated in Ref. [18] and the result is

\[
\nu_{eg} = \frac{3\pi^2 a_0^2 \hbar n_g \gamma}{8m}.
\]

Note that \( \nu_{eg} \) does not depend on \( k \) being a function of volume concentration of helium atoms \( n_g = (MT/2\pi\hbar^2)^{3/2} \exp(-Q/T) \), where \( Q \) is the vaporization energy and \( M \) is the \( ^4 \)He mass. As \( n_g \) is an increasingly exponential function of \( T \), \( \nu_{eg} \) becomes negligible in comparison with \( \nu_{er} \) and \( \nu_{ed} \) for \( T < 1 \) K.

The calculation of \( \nu_{er} \) and \( \nu_{ei} \) is more complicated. Using Eqs. (10) and (11) one can obtain in a straightforward way that both \( \nu_{er}(k) \) and \( \nu_{ei}(k) \) can be written as

\[
\nu_{er(i)}(k) = \frac{m}{\pi \hbar^2 k^2} \int_0^{2k} \frac{q^2 < |\xi_1^{(2)}(q)|^2 > |\chi_1|^{2} |\xi_{er(i)}(q)|^2}{\sqrt{4k^2 - q^2}} dq,
\]

where \( \langle \langle \rangle \rangle \) means an average over ensemble. Considering the electron-ripplon scattering one obtains, from Eq. (10),

\[

\int \left| \xi_1^{(2)}(q) \right|^2 = \frac{\hbar g \tan(\hbar d)}{2\rho \omega_q} (2N_q + 1)
\]

where the ripplon number \( N_q \) is given by the Bose-Einstein function, which leads to \( 2N_q + 1 = \coth(\hbar \omega_q / 2T) \approx 2T / \hbar \omega_q \gg 1 \) for long wavelength ripplons with \( \hbar \omega_q \ll T \). Equation (10) results into

\[
\nu_{er}(k_T x^{1/2}) = \nu_{er(0)} J(x)
\]

where \( \nu_{er(0)} = 8\gamma_0^2 T/\pi \hbar a \) and

\[
J(x) = \frac{x^2}{\pi} \int_0^{\pi/2} \Phi_{er}^2 \left( \frac{v}{\Delta} \sin \theta \right) \sin^6 \theta d\theta + \frac{2}{3} x \int_0^{\pi/2} \Phi_{er} \left( \frac{v}{\Delta} \sin \theta \right) \sin^4 \theta d\theta \sin^2 \theta + \frac{\pi}{18} \Delta^3 \int_0^{\pi/2} [1 - \frac{x_2}{x}] \sqrt{1 + (x_2/x)^2}.
\]

Here

\[
\Phi_{er} = \phi + \frac{\Lambda_1}{\Lambda_0 y^2} [1 + 2\gamma d + 4\gamma_0 (1 + \gamma d) \epsilon^{2\gamma d} E (\xi)]
\]

with

\[
\phi(y) = -\frac{1}{1 - y^2} \left[ \frac{1}{\sqrt{1 - y^2}} \ln \left( \frac{y}{\sqrt{1 + \sqrt{1 - y^2}}} \right) \right] \Theta(1 - y) - \left[ \frac{1}{\sqrt{y^2 - 1}} \arcsin \left( \frac{\sqrt{y^2 - 1}}{y} \right) \right] \Theta(y - 1),
\]

In the above expressions \( \Delta = h^2 \gamma_1^2 / 2m \), \( \Delta_\perp = h^2 \gamma_2^2 / 2m \), \( \gamma_1 = (3m \epsilon_1 E / \hbar^2)^{1/3} \), \( x_c = h^2 \rho_g / 8m T \), \( E (\xi) \) is the exponential-integral function, and \( \Theta(y) \) is the step function.

For the scattering by interface roughness, one obtains

\[
\nu_{ei}(k) = \frac{16m \Lambda_1^2 k^4}{\pi \hbar^2} \int_0^{\pi/2} \sin \theta \left| \langle \xi_2(q) = 2k \sin \theta \rangle \right|^2 \Phi_{ei}^2 \left( \frac{k}{\gamma} \sin \theta \right) d\theta,
\]

where

\[
\Phi_{ei} = \frac{1}{y} \int_0^{\pi/2} x_{K J} [y(x + 2\gamma d)] \exp(-x) dx.
\]

In Eq. (10) and thereafter \( K_J(x) \) is the modified j-order Bessel function. Now we must to choose an interface roughness model to derive the amplitudes \( \xi_{2q} \) appearing in Eq. (10). Following Prange and Nee [2], we use the
Gaussian correlated model, in which the interface roughness is described by two characteristic sizes, the height $\xi_0$ and the lateral length $l$. These parameters define the autocorrelation function for interface roughness which can be written as

$$\langle \xi(r) \xi(r') \rangle = \xi_0^2 \exp \left( -\frac{|r-r'|^2}{l^2} \right)$$  \hspace{1cm} (17)$$

which leads to

$$\langle \xi_{2q} \rangle^2 = \pi \xi_0^2 \ell^2 \exp \left( -\frac{q^2 \ell^2}{4} \right).$$ \hspace{1cm} (18)$$

Assuming this model, the collision frequency, given by Eq. 15, can be calculated and the result is

$$\nu = 32 \pi^2 \xi_0^2 T / h^5$$ \hspace{1cm} (19)$$

where $\nu_0 = 32 m^2 \Lambda^2 \xi_0^2 T / h^5$ and

$$F(b) = b^2 \int_0^{\pi/2} \sin^6 \theta \Phi_{ei}^2 \left( \frac{b}{\gamma l} \sin \theta \right) \exp (-b^2 \sin^2 \theta) \, d\theta.$$ \hspace{1cm} (20)$$

The Gaussian correlated model was employed due to the successful description of the interface roughness for similar systems, for its simplicity and, since there are only two fitting parameters $l$ and $\xi_0$.

**B. Many-electron effects**

Monarkha and co-workers\textsuperscript{22,23,24,25} have studied electron correlation effects in the transport as well quantum magnetotransport of SE on helium by using the force balance transport equation method (FBEM). In this approach the frictional force experienced by the center of mass of the Q2DES due to electron-scatterer interactions is evaluated through the calculation of the momentum rate absorbed by the scatterers. For the system of $N_e$ electrons the kinetic frictional force $F_{fr}$ is given by

$$F_{fr} = N_e e E_{\parallel} = -\frac{dP}{dt},$$ \hspace{1cm} (21)$$

where

$$\frac{dP}{dt} = -\frac{2\pi}{hA} \sum_{\nu, \nu'} (p_{\nu'} - p_{\nu}) \langle \nu', j' | \hat{H}_{int} | \nu, j \rangle^2 \delta((E_{\nu'} + E_{j'}) - (E_{\nu} + E_j)).$$ \hspace{1cm} (22)$$

Here $p_{\nu}$ and $E_{\nu}$ are momentum and energy of scatterer system in the state $|\nu\rangle$, $E_j$ the energy of the electron system in the state $|j\rangle$, $\hat{H}_{int}$ is the Hamiltonian of the interaction between the electron and the particular scatterer. The angle brackets means a thermodynamic average in the laboratory coordinate system. In Ref. 22 it is was shown that $dP/dt$ can be written in terms of the dynamic form factor of the Q2DES

$$S_{lab}(q, \omega) = \frac{2\pi \hbar}{Ne} \left\langle \sum_{j'} (|j'| n_{-j})^2 \delta(E_{j'} - E_{j} - \hbar \omega) \right\rangle$$

in the laboratory frame. $S_{lab}(q, \omega)$ is connected with the form factor $S(q, \omega)$ in the center-of-mass of the electron system, moving at a velocity $u$ relative to the laboratory frame, as $S_{lab}(q, \omega) = S(q, \omega - q \cdot u)$. Here $n_q = \sum_j \exp(-iq \cdot r_j)$. It is important to point out that electron correlations are considered in the system through the many-particle dynamic structure factor which is related to the density-density response function $\chi(q, \omega)$ through the fluctuation-dissipation theorem $S(q, \omega) = -(1/2\pi n_s) \text{coth} (\hbar \omega/2T) \text{Im}[\chi(q, \omega)]$, where $n_s$ is the electron density.\textsuperscript{26}

In the limit of low velocities $u$ satisfying the condition $\hbar q \cdot u \ll T$, we may define an effective collision frequency as a proportionality factor between the momentum loss per unit time of the electron system and the average electron velocity as

$$\frac{dP}{dt} = -n_e \tilde{\nu} u.$$ \hspace{1cm} (23)$$

The effective collision frequency is the sum of frequencies for a particular interaction Hamiltonian $\tilde{\nu} = \tilde{\nu}^{(eg)} + \tilde{\nu}^{(cr)} + \tilde{\nu}^{(ei)}$. The electron mobility is given then by

$$\tilde{\mu} = \frac{e}{m \tilde{\nu}}.$$ \hspace{1cm} (24)$$

Substituting the interaction Hamiltonians, given by Eqs. 2 and 3, into Eq. 22 one obtains

$$\tilde{\nu}^{(eg)} = \frac{3\pi \hbar^2 \alpha^2 n_g}{8 m^3 T} \int_0^\infty q^3 S(q, 0) dq;$$ \hspace{1cm} (25)$$

$$\tilde{\nu}^{(cr)} = \frac{1}{4 \pi m T} \int_0^\infty q^4 \left| \frac{\hbar q \tanh(qd)}{2 \rho \omega_e} \right| \times |\langle \chi_1 | V_{eq}(z) | \chi_1 \rangle|^2 N_q S(q, \omega_q) dq.$$ \hspace{1cm} (26)$$

The calculation of $\tilde{\nu}^{(ei)}$ is done in a similar way to that of $\tilde{\nu}^{(eg)}$ and the result is straightforward

$$\tilde{\nu}^{(ei)} = \frac{1}{4 \pi m T} \int_0^\infty q^4 |\xi_q|^2 \times |\langle \chi_1 | V_{eq}(z) | \chi_1 \rangle|^2 S(q, 0) dq.$$ \hspace{1cm} (27)$$

In the BEFM approach, the form factor $S(q, \omega)$ is essential to the evaluation of $\tilde{\mu}$. Unfortunately $S(q, \omega)$ can be calculated analytically only in the case of the noninteracting electron system and there are no reliable approximate expressions for $S(q, \omega)$ in the whole frequency range in contrast to the static structure factor $S(k) \neq S(k, 0)$ which can be evaluated by appropriate approximation methods. In our calculations, we replace
We have used the parameters for SE mobility over a helium film from Eqs. (8) and (24) and consider the limit 

\[ S(q, \omega) = \left( \frac{2\pi m}{Tq^2} \right)^{1/2} \exp \left( -\frac{\hbar^2 q^2}{8mT} - \frac{m\omega^2}{2Tq^2} + \frac{\hbar\omega}{2T} \right) \]

and consider the limit \( \hbar\omega_q/T \ll 1 \).

IV. RESULTS AND DISCUSSION

Now we present the results of numerical calculations for SE mobility over a helium film from Eqs. (8) and (24). We have used the parameters \( \xi_0 \) and \( \ell \) of the electron-interface scattering to have the best fit to the mobility experimental data. First we must say that the mobility curves in the BEA and FBEM exhibit the same overall behavior independently of the adjustable parameters for the electron-interface interaction. Results for the mobility dependence on the film thickness in the BEA are presented in Fig. 1 for a glass substrate (\( \varepsilon_s = 7.3 \)) for \( T = 1.5 \) K and the fitting parameters \( \xi_0 = 10 \) Å and \( \ell = 1420 \) Å. For a sake of comparison, we plot the mobility data taken from Ref. 13. One can see the decisive role of electron-interface scattering and the best fit is attainable for \( d \lesssim 300 \) Å, where, as expected, the influence of roughness is more pronounced. We also show separately the contributions to the mobility coming from electron-ripplon and electron-atom scattering processes. We observe that neither electron-gas nor electron-ripplon scattering mechanisms can explain the experimental data for wide range of \( d \). By fitting the experimental data with mobility calculations in the FBEM, we obtain the best results for \( \xi_0 = 6.45 \) Å and \( \ell = 5000 \) Å.

In Fig. 2 we depict, in a similar way to Fig. 1, mobility curves as a function of the film thickness for solid neon (\( \varepsilon_s = 1.19 \)) and \( T = 1.2 \) K. The best fit of experimental data is achieved for \( \xi_0 = 180 \) Å and \( \ell = 300 \) Å in BEA and \( \xi_0 = 85 \) Å and \( \ell = 300 \) Å in FBEM. We see now that \( \xi_0 \) and \( \ell \) are of the same order of magnitude of \( d \) which makes unjustifiable the approximation \( |\xi_0(r)|/d \ll 1 \) which supports the perturbative approach to obtain the potential \( V_{\text{eq}}(z) \) of Eq. (6), and, hence, the applicability of Born approximation for the description of electron-interface scattering. We would guess that the neon surface, being much rougher than the glass one, it has more irregularities leading to significant fluctuations of \( d \). Moreover, we observe a worse agreement between the theoretical curve and experimental data at large \( d \), where the electron-ripplon and electron-gas mechanisms would dominated the scattering.

The temperature dependence of SE mobility is depicted in Fig. 3 where the same values for \( \xi_0 \) and \( \ell \) obtained by fitting \( \mu(d) \) are used. As it can be seen we get rather good agreement with the experimental data of Ref. 12 for \( d = 350 \) Å. However the agreement becomes less satisfactory for smaller \( d \). By considering only the electron-ripplon and electron-atom scattering we found a difference of about more than one order of magnitude between the calculation results and the experimental ones. Unfortunately, to our knowledge, there is no experimental data on the temperature dependence of SE mobility in the case of a film over solid neon.

Figure 4 shows the influence of the dielectric constant
of the substrate on the SE mobility calculated within the BEA. We used here the same values of $\xi_0$ and $l$ as in Fig. 1 for both glass and pmma ($\varepsilon_s = 2.2$) substrates. We see that the mobility varies inversely with respect to $\varepsilon_s$ for whole of temperatures considered. This is a direct consequence from $\Lambda_1 \sim \varepsilon_s$ appearing in the collision frequencies which in turn are in the denominator of the mobility formulas [Eqs. (8) and (24)].

In order to make clearer the role of different scattering mechanisms we present in Fig. 5 the SE mobility, calculated within the FBEM, as a function of temperature for a film over glass and $d = 350$ Å. The calculated mobility curves are shown when the distinct scattering processes are considered separately. As it can be seen, the inclusion of roughness interface scattering is essential to explain the experimental data. The nonmonotonic dependence of SE mobility must be attributed to the crucial role of electron-interface scattering since it is well known that the mobility limited only by electron-ripplon and electron-gas scattering is a monotonuous decreasing function of temperature.

Finally, we compare the mobility results obtained in the two different methods used here by depicting the curves of $\mu(d)$ and $\mu(T)$ in Figs. 6 and 7 respectively for the case of a glass substrate. We plot also with the experimental data. Smaller values of $\xi_0$ obtained in FBEM as compared with those in BEA fulfill more satisfactorily the condition $|\xi_2(r)|/d \ll 1$. We observe much better agreement between experimental data and theo-
FIG. 7: Mobility as a function of temperature. The notations are the same as in Fig. 6.

tical curves calculated in FBEM for the same values of $\xi_0$ and $I$. We point out that the numerical results within the FBEM are the same as those obtained in the complete control approximation (CCA). In the CCA, the mobility is calculated with the BEA, but in the regime where the electron-electron collision frequency is much higher than the collision frequency due to other mechanisms. The electrons are supposed to redistribute their momenta, due to collisions between electrons, in such a way that the momentum of the total system does not change but electrons acquire the same drift velocity. The coincidence of results indicates that in order to establish the specific role of electron-electron interactions we must go beyond the noninteracting dynamical structure factor for calculating the mobility in the FBEM as given by Eq. (28).

Our conclusions then are valid only in the low or intermediate electron density regime.

V. CONCLUDING REMARKS

In this work we have studied the dependence of the mobility of surface electrons over a liquid helium film on the temperature and on the film thickness. The transport properties are determined from the solution of the Boltzmann equation in the relaxation time approximation and in the force balance equation. We employed the Gaussian correlated model to describe the interface roughness between the film and the substrate. The parameters are adjustable through the evaluation of both temperature and film thickness dependencies of the mobility. The values obtained for the strength and range of the rough interface are of the order of few atomic layers and 100 Å respectively which are reliable and in the mesoscopic regime. We showed that the SE mobility is limited by the roughness scattering because electron-ripplon and electron-gas atom scattering cannot explain the experimental data. However, we cannot rule out the presence of other mechanisms as SE localization by potential wells caused by the underlying solid substrate.

VI. ACKNOWLEDGMENT

We are indebted to Professor A. J. Dahm, whom forthwith provides us values of specific constants. This work was supported by CNPq and FAPESP, Brazil.
