Electrospun Nb-doped TiO$_2$ nanofiber support for Pt nanoparticles with high electrocatalytic activity and durability

MinJoong Kim$^{1,*}$, ChoRong Kwon$^{2,3,*}$, KwangSup Eom$^4$, JiHyun Kim$^3$ & EunAe Cho$^1$

This study explores a facile method to prepare an efficient and durable support for Pt catalyst of polymer electrolyte membrane fuel cell (PEMFC). As a candidate, Nb-doped TiO$_2$ (Nb-TiO$_2$) nanofibers are simply fabricated using an electrospinning technique, followed by a heat treatment. Doping Nb into the TiO$_2$ nanofibers leads to a drastic increase in electrical conductivity with doping level of up to 25 at. % (Nb$_{0.25}$Ti$_{0.75}$O$_2$). Pt nanoparticles are synthesized on the prepared 25 at. % Nb-doped TiO$_2$-nanofibers (Pt/Nb-TiO$_2$) as well as on a commercial powdered carbon black (Pt/C). The Pt/Nb-TiO$_2$ nanofiber catalyst exhibits similar oxygen reaction reduction (ORR) activity to that of the Pt/C catalyst. However, during an accelerated stress test (AST), the Pt/Nb-TiO$_2$ nanofiber catalyst retained more than 60% of the initial ORR activity while the Pt/C catalyst lost 65% of the initial activity. The excellent durability of the Pt/Nb-TiO$_2$ nanofiber catalyst can be attributed to high corrosion resistance of TiO$_2$ and strong interaction between Pt and TiO$_2$.

Polymer electrolyte membrane fuel cell (PEMFC) is an electrochemical energy conversion device to produce electricity from hydrogen and oxygen. The PEMFC has advantages of high efficiency and environmental friendliness and attracts much attention as a power source for homes, buildings and transportations. However, the high fabrication cost and short lifespan are still major obstacles for commercialization. Among the various components of the PEMFC, electrode materials play a substantial role in determining the cost and durability. Therefore, development of well-performing and durable electrode materials has been a main concern in the PEMFC research area.

The most widely used electrode material for PEMFC is Pt nanoparticles supported on powdered carbon black (Pt/C), which can significantly reduce Pt usage compared with unsupported Pt black. As a support material, carbon has merits of low cost and high electrical conductivity$^1$ and demerits of corrosion and low durability$^2$. Particularly during start-up and shut-down of a PEMFC stack, carbon supports in the cathode are subjected to a severe corrosion environment via the following reaction$^2$:

$$C + 2H_2O \rightarrow CO_2 + 4H^+ + 4e^- \quad (E^0 = 0.207 \text{ V}_{\text{NHE}} \text{ at } 25^\circ\text{C}). \quad (1)$$

As carbon supports corrode to form carbon dioxide, Pt nanoparticles originally sitting on the carbon supports collapse and agglomerate$^{3,4}$. Loss of the Pt catalysts due to carbon corrosion leads to drastic performance decay$^{5-7}$. The cathode carbon corrosion is known as one of the crucial sources for degradation of PEMFC, particularly in automotive applications$^8$. Therefore, in order to enhance durability of PEMFC, it is strongly required to replace...
carbon with the material which has high electrical conductivity and high corrosion resistance under the fuel cell operating conditions.

As candidate support materials, conductive or semi-conductive metal oxides such as ITO\(^{10}\), SnO\(_2\)^{11,12}, WO\(_x\)^{13–15} and TiO\(_x\)^{16–21} have been studied. In addition to the excellent corrosion resistance, those materials are expected to enhance stability of Pt catalyst owing to the strong surface interaction between metal oxides and Pt nanoparticles\(^{15}\).

Among those metal oxides, titanium oxide (TiO\(_2\)) has attracted consideration as a novel support material due to its stability in the fuel cell operation condition, low cost, commercial availability and the ease of controlling its shape and structure. However, since pure TiO\(_2\) is a semiconductor with a band gap energy of 3.2 eV (anatase) and 3.0 eV (rutile)\(^{22}\), its electrical conductivity has to be enhanced to be used as a catalyst support material.

Doping of n-type dopants, whose atomic radius is similar to that of Ti, can increase the electrical conductivity of TiO\(_2\). Nb, which exhibits a pentavalent ionic state, is the most commonly used n-type dopant for TiO\(_2\)^{23–25}. It was reported that Nb-doped TiO\(_2\) (Nb-TiO\(_2\)) has sufficient electrical conductivity for catalyst support material and Pt catalysts supported on Nb-TiO\(_2\) exhibit enhanced durability compared with those on the commercial carbon\(^{26–30}\). In most of the previous studies, Nb-TiO\(_2\) was synthesized using solution-based processes such as the hydrothermal\(^{27}\), sol-gel route\(^{28,29}\) and template-assisted multiple-step\(^{26,30}\). However, these methods have low product yield and consist of complicated procedures possibly leading to low reproducibility.

In this study, we aimed to develop a facile and scalable fabrication method for Nb-TiO\(_2\) support for Pt catalyst with high electrochemical stability and high electrical conductivity. So, we synthesized Nb-TiO\(_2\) nanofibers using the electrospinning technique, which is known as a facile, cost-effective, and scalable method for the synthesis of metal oxide nanofibers\(^{31}\). Moreover, the anisotropic 1-D structure of electrospun nanofiber is suitable for a catalyst support due to its high surface area\(^{32}\). To attain high electrical conductivity, the synthesis procedure of Nb-TiO\(_2\) nanofibers was examined with regard to the calcination temperature and Nb doping level. Electrocatalytic activity and durability of Pt catalyst supported on the Nb-TiO\(_2\) nanofibers were evaluated in comparison with Pt catalyst supported on a powered carbon black.

Results

Synthesis of Nb-TiO\(_2\) nanofibers. TiO\(_2\) and Nb-TiO\(_2\) nanofibers were obtained by calcining as-spun nanofibers in air at 700 °C for 1 h. The calcination condition was optimized based on synthesis of pure TiO\(_2\) nanofibers as shown in Figs S1–3. At 700 °C, anatase was fully transformed into stable rutile (Fig. S2). Fig. 1 (a–d) present SEM and TEM images of the TiO\(_2\) and the Nb-TiO\(_2\) nanofibers with Nb doping levels of 10, 25, and 50 at. %. Nb doping level was defined as an atomic ratio of Nb to (Nb + Ti). As shown in SEM images, all of the samples have a similar and uniform 1-D nanostructure of approximately 100 nm in diameter. Ti and Nb ions are also uniformly distributed throughout the nanofibers irrespective of Nb content (Fig. S4). However, Nb-TiO\(_2\) nanofibers have smaller crystallites than the TiO\(_2\) nanofiber as demonstrated in TEM images (Fig. 1 inset images).

Figure 2(a) present XRD patterns for the TiO\(_2\) and the Nb–TiO\(_2\) nanofibers. Changes in crystal structure by Nb doping were observed in the XRD patterns; i) peak intensities of the Nb–TiO\(_2\) nanofibers were significantly lower than those of the TiO\(_2\) nanofibers, ii) anatase phase appeared in the Nb–TiO\(_2\) nanofibers unlike the TiO\(_2\)
nanofiber with perfect rutile. The decrease in peak intensity by Nb doping resulted from the reduction in crystallite size as observed in Fig. 1. Presence of anatase phase in the Nb-TiO₂ nanofibers can be associated with Nb ions. It was reported that doped Nb ions hinder diffusion of Ti ions required for crystal growth and anatase-rutile phase transformation33,34, leading to the decrease in the crystallite size and the appearance of anatase phase in the Nb-TiO₂ nanofibers.

Compared to the TiO₂ nanofiber, 10 at. % Nb-TiO₂ nanofiber exhibited anatase peaks very clearly. However, with increasing Nb content from 10 to 25 at. %, anatase peaks diminished. When Nb doping level increased further to 50 at. %, both of rutile and anatase peaks diminished with increase in Nb oxide peaks, such as Nb₂O₅. It is known that Nb ions can be expelled from TiO₂ when Nb doping exceeds a certain level33. Thus, anatase-rutile phase transformation can resume in the 25 at. % Nb-doped TiO₂ nanofibers, which causes the decrease in anatase peak intensity. 50 at. % Nb-TiO₂ could be a composite with a large amount of Nb-oxides due to increased expulsion of Nb ions. These results are in a good agreement with the previous results on the anatase-to-rutile phase transition of TiO₂ by Nb doping33.

Figure 2(b) shows the effect of the Nb doping level and calcination temperature on the electrical conductivity of the Nb-TiO₂ nanofibers. With increasing Nb content from 0 to 25 at. %, the electrical conductivity greatly increased reflecting that 25 at. % Nb-TiO₂ nanofiber contains higher doping level of Nb than in 10 at. % Nb-TiO₂. However, the electrical conductivity was lowered with 50 at. % Nb content due to the formation of a large amount of Nb-oxides as observed in the XRD patterns32. The formation of Nb-oxides from expelled Nb ions could lower the Nb doping efficiency into TiO₂ phase, which lead to the decrease in electrical conductivity.

To understand the contribution of Nb doping to electrical conduction of TiO₂, Ti 2p and Nb 3d spectra of 0, 10, 25, and 50 at. % Nb-TiO₂ nanofibers were measured by XPS as shown in Fig. 2(c) and (d). All of the Nb-TiO₂ nanofibers have the same peak position of Ti 2p₃/₂ at 459.3 eV corresponding to Ti⁴⁺ valence and Nb 3d₅/₂ peak at 207.2 eV corresponding to Nb⁵⁺ valence state regardless of Nb doping level. These results imply that when Nb⁵⁺ ions substitute for Ti⁴⁺ ions, charge compensation occurs by creation of one Ti cation vacancy per four Nb ions rather than by reduction of Ti⁴⁺ to Ti³⁺, as described in the following equation35:

\[ \frac{1}{2}Nb₂O₅ + Ti^{x+} \rightarrow Nb^+ + TiO_2 + 1/4V^{4+} + TiO_2 + 1/4O_2 \]  

(2)

Thus, by Nb-doping up to 25 at. %, Ti cation vacancies are formed in TiO₂ crystalline nanofibers and contribute to the significant increase in electrical conductivity. Based on those results, Pt nanoparticles were synthesized on the 25 at. % Nb-TiO₂ nanofibers and on a commercial Vulcan carbon.
Electrochemical characterization. Figure 3(a–d) shows the oxygen reduction reaction (ORR) and the cyclic voltammograms (CVs) polarization plots for Pt/Nb-TiO2 nanofiber catalyst and Pt/C catalyst before and after an accelerated stress test (AST). The ORR polarization plots were measured in O2-saturated 0.1 M HClO4 solution at a scan rate of 5 mV s⁻¹ with a rotating speed of 1600 rpm. The CVs were measured in Ar-saturated 0.1 M HClO4 solution at a scan rate of 20 mV s⁻¹. As an AST, voltage cycling was conducted repetitively between 0.6 and 1.1 V_RHE in an O2-saturated 0.1 M HClO4 solution at a scan rate of 50 mV s⁻¹.

Before the AST, there is little difference in the ORR activity between the Pt/Nb-TiO2 nanofiber catalyst and the Pt/C catalyst. Half-wave potentials obtained from each ORR polarization curve are also almost same; 0.896 for the Pt/Nb-TiO2 nanofiber and 0.895 V_RHE for the Pt/C catalyst. To precisely compare the initial electrocatalytic activity of the Pt/Nb-TiO2 nanofiber catalyst and the Pt/C catalyst, we calculated the kinetic current density at 0.9 V_RHE. The kinetic current density \( i_k \) is expressed as Eq. (3).

\[
\frac{1}{i} = \frac{1}{i_k} + \frac{1}{i_l}
\]

The initial mass activity of the Pt/Nb-TiO2 nanofiber catalyst at 0.9 V_RHE (81 A g_Pt⁻¹) was slightly higher than that of the Pt/C catalyst (73.8 A g_Pt⁻¹). It is well established for metal-oxide supported catalysts that strong metal-support interactions (SMSI) can enhance catalytic activity and durability of the Pt catalysts toward ORR. Those results demonstrate that the Pt/Nb-TiO2 nanofiber catalyst exhibits excellent ORR activity...
comparable with the Pt/C catalyst, and the Nb–TiO₂ nanofiber has sufficient conductivity and surface area to serve as a catalyst support.

During the AST, ORR activity also decreased with repeating voltage cycles as shown Fig. 3(a) and (b). It is notable that the decrease in ORR activity is much faster for the Pt/C catalyst than for the Pt/Nb-TiO₂ nanofiber catalyst during the AST. Half-wave potential of the Pt/Nb-TiO₂ nanofiber catalyst decreased only by 17 mV, whereas that of the Pt/C catalyst decreased by 40 mV during 6,000 cycles. The hydrogen adsorption/desorption peak area of CVs also gradually decreased with repeating voltage cycles as shown in Fig. 3(c) and (d), indicating a decrease in electrochemical surface area (ECSA) of Pt. The mass activity of the Pt/Nb-TiO₂ nanofiber catalyst measured at 0.9 V_RHE decreased from 81 to 52 A g⁺⁻¹ while that of the Pt/C drastically decreased from 73.8 to 25.9 A g⁺⁻¹. The Pt/Nb-TiO₂ nanofiber catalyst retained more than 60% of the initial ORR activity while the Pt/C catalyst lost almost 65% of the initial activity during the AST. During the same potential cycles, ECSA of the Pt/Nb-TiO₂ nanofiber, which is calculated from the hydrogen adsorption/desorption peak, decreased by about 32%, whereas that of the Pt/C catalyst decreased by about 53% of the initial values. The Pt/Nb–TiO₂ nanofiber catalyst has remarkably enhanced durability than the Pt/C catalyst.

Figure 4 presents TEM images of the Pt/Nb–TiO₂ nanofiber catalyst and the Pt/C catalyst before and after the AST. For the Pt/Nb–TiO₂ nanofiber catalyst, the Pt nanoparticles on the Nb–TiO₂ nanofiber negligibly agglomerated and still uniformly distributed after the AST. In contrast, the Pt nanoparticles on the carbon support heavily agglomerated and the mean particle size increased to 5.4 nm from 4.1 nm during the AST. In addition to the agglomeration of Pt nanoparticles, significant amount of Pt nanoparticles on the carbon support could be dissolved, resulting in the significant losses in ORR activity and ECSA of the Pt/C catalyst as shown in Fig. 3. The enhanced durability of the Pt/Nb–TiO₂ nanofiber catalyst would be attributed to: (a) the higher corrosion resistance of the Nb–TiO₂ nanofiber support compared with carbon at high potential in acidic environments and
was 10 cm, and applied voltage was 20 kV. Because of the external electrostatic field and electrostatic repulsion, the Pt/Nb-TiO2 nanofiber was washed with D.I. water and then dried at 40 °C for 24 h. For comparison, Pt catalyst, the ECSA of Pt/Nb-TiO2 nanofiber catalyst decreased by about 32% while that of the Pt/C decreased about by 53% of the initial values. Thus, it can be concluded the Nb-TiO2 nanofiber catalyst exhibit similar initial electrocatalytic activity but much higher durability compared with the Pt/C catalyst.

**Discussion**

As an efficient and durable catalyst support material for polymer electrolyte membrane fuel cell (PEMFC), Nb-TiO2 nanofibers were simply synthesized using the facile electrospinning followed by the heat treatment. TiO2 nanofibers prepared by calcining the as-spun precursor solution at 700 °C in air atmosphere. Doping Nb into TiO2 leads to a drastic increase in the electrical conductivity up to 25 at. %. A further increase in the Nb content lowered the electrical conductivity owing to formation of a large amount of Nb oxides. Based on those results, Pt nanoparticles were fabricated on the 25 at. % Nb-doped TiO2 nanofibers calcined at 700 °C in air for 1 h and on a commercial Vulcan carbon for comparison.

Electrocatalytic activity and durability of those prepared catalysts were evaluated in terms of mass activity toward the ORR and ECSA. Pt/Nb-doped TiO2 nanofiber catalyst exhibited excellent ORR activity comparable with Pt/C catalyst (81 A gPt−1). Those results are the highest value among the TiO2-supported Pt catalysts up to date16–21,26–29. During 6,000 potential cycles between 0.6 and 1.1 V RHE, the mass activity measured at 0.9 V RHE decreased from 81 to 52 A gPt−1 for the Pt/Nb-TiO2 nanofiber catalyst and from 73.8 to 25.9 A gPt−1 for the Pt/C catalyst, the ECSA of Pt/Nb-TiO2 nanofiber catalyst decreased by about 32% while that of the Pt/C decreased about by 53% of the initial values. Thus, it can be concluded the Nb-TiO2 nanofiber catalyst exhibit similar initial electrocatalytic activity but much higher durability compared with the Pt/C catalyst.

**Materials and Methods**

**Preparation of Nb-TiO2 nanofiber support.** To prepare an Nb-TiO2 precursor solution, 4 ml of acetic acid (≥99.7%), 2 ml of titanium tetraisopropoxide (TTIP, 97%), 2 g polyvinylpyrrolidone (PVP, Mw = 1,300,000), and appropriate amount of niobium ethoxide (99.95%) for 0, 10, 25, and 50 at. % Nb doping were added to 14 ml of ethyl alcohol (EtOH, anhydrous). Then, the prepared solutions were degassed by sonication for 5 min and transferred to an injector for electrospinning.

The Nb-TiO2 precursor solution was fed at a constant rate of 3 ml h−1 through a stainless steel needle with a flat outlet. Diameter of the needle was 27 G (200 µm). Distance between the tip of the needle and the collector plate was 10 cm, and applied voltage was 20 kV. Because of the external electrostatic field and electrostatic repulsion between the surface charges, a so-called ‘Taylor cone’ was formed at the tip of the needle instead of a droplet. During electrospinning, the effects of the surface tension were outbalanced by the electrostatic interactions, and a liquid jet was formed. The needle was slowly moved along two perpendicular paths to randomly deposit the TiO2 nanofibers on the aluminum foil, which was placed on top of the collector plate. The as-spun nanofibers were dried at room temperature for 15 hours and then calcined in air at 600, 700, 800, 900 °C, respectively, for 1 h to convert the TTIP into crystalline TiO2 and to completely remove PVP and remaining solvents.

**Synthesis of Pt catalyst on Nb-TiO2 nanofiber and carbon supports.** Pt catalyst was synthesized on Nb-TiO2 nanoparticle support (denoted Pt/Nb-TiO2 nanofiber) using the borohydride reduction method. Firstly, H2PtCl6·6H2O (Pt precursor) was dissolved in EtOH. The prepared Nb-TiO2 nanofiber support was dispersed in EtOH and then mixed with the prepared Pt precursor solution by mechanical stirring. Then, pH value of the mixed suspension was adjusted to 8.5 by adding 0.5 M KOH or 0.5 M HCl solution. The Pt precursor was reduced by adding excess amount of 0.1 M NaBH4 solution to the mixed solution and being stirred for 2 h. The prepared Pt/Nb-TiO2 nanofiber was washed with D.I. water and then dried at 40°C for 24 h. For comparison, Pt catalyst was fabricated on a commercial Vulcan carbon (Pt/C) using the modified ethylene glycol method. Pt precursor solution was prepared as described above27. Pt loading on Nb-TiO2 nanofiber was 20 wt. %, and on Vulcan carbon was 40 wt. %. To adjust Pt particle size on Vulcan carbon to 4 nm, we had to increase Pt content to 40 wt. %. Pt content in the prepared samples was measured by inductively coupled plasma-mass spectroscopy (ICP-MS).

**Physical characteristics.** To determine calcination temperature, thermogravimetric analysis (TGA) was conducted for the as-spun nanofibers from 20 to 900 °C at a heating rate of 10 °C min−1 under an air atmosphere. Electrical conductivity of the calcined TiO2 nanofibers was obtained from I-V measurement using a 2-point probe equipment as shown in Fig. S5. Crystal structure of the samples were analyzed from X-ray diffraction (XRD) (Bruker D-8 advance) spectra. The diffraction spectra were recorded using Cu-Kα (λ = 1.5046 Å) radiation (20 kV and 20 mA) from 20 angles of 20° to 80° with a step size of 0.04° at a rate of 2° min−1.

Morphology of the samples was observed using environmental field emission-secondary electron microscopy (FE-SEM) and field emission-transmission electron microscopy (FE-TEM). Chemical composition of the Nb-TiO2 nanoparticle was measured using the energy dispersive X-ray analysis (EDAX) detector in the SEM or TEM. From X-ray photoelectron spectroscopy (XPS), elemental composition, chemical state and electronic state of the elements were analyzed.

**Electrochemical characterization.** Electrochemical experiments were performed in a conventional three-electrode cell. The working electrode was catalyst-coated glassy carbon. The counter electrode was a platinum wire and a saturated calomel electrode (SCE) was used as the reference electrode. All the potentials were represented on the scale of the reversible hydrogen electrode (RHE). To prepare the catalyst ink for the working electrode, 5 mg of Pt/C and 10 mg of Pt/Nb–TiO2 nanofiber catalysts were ultrasonically suspended in 800 µl of isopropyl alcohol (IPA) and 60 µl of Nafion solution (5 wt. % solution, Aldrich). Then, 5 µl of ink was transferred using a micropipette onto a glassy carbon rotating disk electrode (RDE, 5 mm diameter) and dried. Cyclic voltammetry (CV) was carried out in the potential range between 0.05 and 1.0 V RHE at a scan rate of 20 mV s−1 in Ar-saturated 0.1 M HClO4 solution. Electrochemical active surface (ECSA) was estimated based on
the \( H_2 \) desorption peaks observed at potentials from 0.05 and 0.35 \( V_{\text{RHE}} \). The hydrogen desorption charge was assumed to be 0.21 mC cm\(^{-2}\).

Activity of the prepared catalyst for the oxygen reduction reaction (ORR) was measured in O\(_2\)-saturated 0.1 M HClO\(_4\) solution at room temperature. The RDE rotating rate was 1600 rpm, and the sweep rate was 5 mV s\(^{-1}\). As an accelerated stress tests (AST), potential cycling was conducted in the potential range from 0.6 to 1.1 \( V_{\text{RHE}} \) in the O\(_2\)-saturated 0.1 M HClO\(_4\) solution at a scan rate of 50 mV s\(^{-1}\).

Acknowledgements
This work was supported by the Korea Institute of Energy Technology Evaluation and Planning (KETEP) funded by the Ministry of Trade, Industry & Energy (No. 20153010041750), and the National Research Foundation (NRF) of Korea (No. 2015056558).

Author Contributions
All authors designed the research. MinJoong Kim and ChoRong Kwon performed the experiments, analyzed the data. KwangSup Eom and JiHyun Kim carried out special experimental work and analyzed the data. MinJoong Kim and EunAe Cho co-wrote the manuscript. All authors contributed to editing the manuscript.
