Keywords: Critically ill adults, Intensive care, Malnutrition, Nutritional assessment, Nutritional status.

Indian Journal of Critical Care Medicine (2020): 10.5005/jp-journals-10071-23617

Introduction

In critically ill patients, the prevalence of malnutrition ranges between 38% and 78%. At admission to hospital, at least one-third of patients have some degree of malnutrition and two-thirds of them progress to further decline without adequate nutritional provision. Additionally, two-thirds of patients who were without malnutrition will become malnourished during hospitalization. Many studies have shown that malnutrition is an independent risk factor for nosocomial infections and higher readmissions rates. Early identification and appropriate nutritional intervention in malnourished patients has consistently shown to decrease hospital stay, infectious complications, and overall cost. Nutritional assessment in critically ill patients is challenging, best method to identify patients susceptible to malnutrition has not yet been identified. Various risk factors and nutritional risk scores have been proposed. In this review article, we will be discussing briefly on the pathophysiology of malnutrition, the importance of nutritional risk screening (NRS 2002) and assessment, and finally the practical implications of bedside nutritional assessment.

Malnutrition in Critically Ill: Pathophysiology

Malnutrition is defined as any variation in degree of nutrition (either overnutrition or undernutrition) with or without inflammation that has led to variations in body composition. According to a consensus statement by the Academy of Nutrition and Dietetics (AND) and the American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.) malnutrition is defined as the presence of any two or more of these entities: Insufficient energy, intake, weight loss, loss of muscle mass, loss of subcutaneous fat, localized or generalized fluid accumulation, or decreased functional status. Critical illness is a life-threatening condition characterized by infection, trauma, or any medical illness. It involves massive surge of proinflammatory mediators, which incites host catabolism. Proinflammatory response to infection or trauma is body’s adaptive mechanism to defend against pathogens and to supplement substrates for healing. However, severe proinflammatory response is counterproductive; hence, body mounts an anti-inflammatory response to counterbalance the damage. On occasions when the balance shifts toward excess anti-inflammatory state, the immune parallel thus created may not be effective enough to eradicate the pathogens. Therefore, a delicate balance should exist between pro- and anti-inflammatory states to facilitate appropriate host immune response. Nutrition plays a vital role in modulating host immune response, maintaining muscle mass, slowing catabolism, and maintaining gastrointestinal mucosal integrity and immunity (Flowchart 1).

For better understanding, the pathophysiology of malnutrition can be discussed in two entities: Stress catabolism and inadequate nutrition intake. In critical illness, catabolic hormones and proinflammatory mediators are released to enhance catabolism. Catabolic hormones, such as, glucagon, cortisol, and catecholamines, are secreted and nutrition reserves will be mobilized. There will be generation of endogenous substrates like glucose, amino acids, and free fatty acids. These substrates will be delivered to sustain function of the vital organs. Proinflammatory mediators like IL-1, IL-6, and TNF-alpha that are produced as a result of infection or injury will further exaggerate catabolism. During such states, the priority is to provide adequate nutrition support to optimize function of vital organs and to promote appropriate host immune response. In addition, most critically ill patients have a lower nutritional reserve, compounding to the restricted food intake during intensive care unit (ICU) and hospital stay, prolonged fasting and frequent interruptions in feeding further promote iatrogenic underfeeding and worsening malnutrition. Early identification and prompt initiation of feeding can hasten the recovery from critical illness. Few early indicators of malnutrition are mentioned in the Table 1.

There are two steps needed for the diagnosis of malnutrition. The first step requires a validated screening tool to identify patients at risk of malnutrition and the second step involves its diagnosis and grading the severity of malnutrition.

Nutritional Risk Screening

Nutritional screening is performed to critically ill patients to identify the patients at high risk of malnutrition. American Society for Parenteral and Enteral Nutrition has defined nutritional screening as “A process to identify an individual who is malnourished or who is at risk for malnutrition to determine if a detailed nutrition assessment is indicated.” Screening is best done within 24 to 48 hours of hospital admission by the treating doctors. Screening can

**Table 1: Patients at risk of malnutrition**

| Criteria                                                                 |
|--------------------------------------------------------------------------|
| Being grossly underweight (<80% ideal body weight).                      |
| Being grossly overweight (>120% ideal body weight).                     |
| Recent weight loss (>10% over 3 months).                                |
| Being alcoholic/substance dependent.                                    |
| Nil permouth for >5 days.                                                |
| Increased nutrient losses.                                               |
| Malabsorption.                                                           |
| Short bowel syndrome.                                                    |
| Fistulae.                                                                |
| Draining abscesses or wounds/burns.                                     |
| Renal dialysis.                                                          |
| Increased nutrient requirements.                                         |
| Trauma.                                                                 |
| Burns.                                                                  |
| Sepsis.                                                                 |
| Taking medication with anti-nutrient properties.                        |

**Nutritional Risk Screening 2002**

The nutritional risk screening 2002 (NRS 2002) was developed by Kondrup et al.\(^{16}\) The Dutch group developed the tool which included recent dietary intake, disease severity, and weight loss. A NRS score of \( \geq 3 \) indicated severe risk of malnutrition and NRS score of 0 indicated absence of malnutrition. The screening tool was validated in many previously published randomized control trials. A high NRS 2002 score was able to predict poor outcome in non-critically ill patients but not in critically ill patients.\(^{15}\) The assessment of weight loss and dietary intake may be difficult in critical care settings. One of the main limitations of the NRS 2002 score is that any critically ill patient with APACHE II score above 10 will fall in the high-risk category (Tables 2 to 4).

**Nutrition Risk in the Critically Ill**

Heyland et al.\(^{18}\) developed a screening tool for critically ill patients. Previous screening tools implicated all critically ill patients in high-risk category and no screening tool was studied exclusively in critically ill population. Heyland et al.\(^{18}\) in a prospective observational multicenter study, data were collected, and a multivariable model was developed. The authors selected the parameters based on a conceptual model of malnutrition in critically ill including inflammatory markers, severity illness scores, and developed the scoring system. The NUTRIC score was able to discriminate critically ill patients who will benefit from aggressive protein energy provision. This was the first screening tool that was validated and developed in critically ill patients. The score can be easily calculated with parameters measured in daily care of critically ill patients.
ill patients. Addition of IL-6 marker was called as modified NUTRIC score by the authors. However, the addition of IL-6 did not improve the discriminative ability of the score; hence, the authors suggest using the score also when IL-6 values are not available.18

The A.S.P.E.N./society of critical care medicine guidelines suggest using either NRS 2002 or NUTRIC/m NUTRIC for nutritional screening in critically ill patients.19 The NUTRIC score is more useful in critically ill patients as it was developed in critically ill patients and recent food intake and weight change which is difficult to obtain in ICU patients were not included. The limitations of the NUTRIC score were that it did not include nutritional parameters and also micronutrient deficiencies were not included. The NUTRIC score is still not prospectively tested in a randomized control trial. The NUTRIC score performed better as compared to the MUST score in critically ill patients.20 Comparative studies between NUTRIC and NRS 2002 scores showed inconsistent results. In one retrospective study, NRS 2002 showed higher sensitivity and specificity for the diagnosis of malnutrition when compared to NUTRIC score,21 while another retrospective study by Canales et al.22 found that NUTRIC score was superior to NRS 2002 for assessing malnutrition risk. An observational study by Coltman et al.23 found that NUTRIC score was no different to routine screening. In a recent observational study, NUTRIC score was also able identify high-risk critically ill COVID-19 patients.24

## Table 2: Nutritional risk screening and assessment tools that have been studied14

| Instrument | Anthropometry and/or diet related | Severity of illness |
|------------|----------------------------------|---------------------|
| Birmingham nutrition risk score | Weight loss, BMI, appetite, ability to eat | Stress factor (severity of diagnosis) |
| Malnutrition screening tool | Appetite, unintentional weight loss | Presence of acute disease |
| Malnutrition universal screening tool | BMI, change in weight | Albumin, prealbumin, lymphocyte count |
| Maastricht index | Percentage ideal body weight | |
| Nutrition risk classification | Weight loss, percentage ideal body weight, dietary intake | |
| Nutritional risk index | Present and usual body weight | |
| Nutritional risk screening 2002 | Weight loss, BMI, food intake | |
| Prognostic inflammatory and nutritional index | Triceps skinfold | |
| Prognostic nutritional index | BMI, percentage weight loss | Albumin |
| Simple screening tool | Recent weight history, appetite, use of oral supplement or tube feeding | Diagnosis (severity) |
| Short nutrition assessment questionnaire | | Albumin, prealbumin, C-reactive protein, α1-acid glycoprotein |
| NUTRIC (nutrition risk in the critically ill) | Nil | Albumin |
| Mini nutritional assessment | Weight, height, mid-arm and circumference, diet history, appetite, feeding mode | Albumin, transferrin, skin sensitivity |
| Subjective global assessment (SGA) | Weight and diet history | Albumin |

## Table 3: Nutritional risk screening 200216,17

| Nutritional status | Score | Stress metabolism (severity of disease) | Score |
|--------------------|-------|----------------------------------------|-------|
| None | 0 | None | 0 |
| Moderate | 2 | Moderate stress metabolism | 2 |
| Weight loss >5% in 2 months | | Patient is bedridden due to illness | |
| BMI 18.5–20.5 kg/m² AND Reduced general condition OR 25–50% of the normal food intake in the last week | | Highly increased protein requirement | |
| Severe | 3 | Severe stress metabolism | 3 |
| Weight loss >5% in 1 month OR | | Patient is critically ill (intensive care unit) | |
| BMI <18.5 kg/m² AND reduced general condition OR 0–25% of the normal food intake in the last week | | Very strongly increased protein requirement can only be achieved with parenteral nutrition | |

Total (A) Total (B) Age = <70 years: 0 pt, ≥70 years: 1 pt Total = (A) + (B) + Age ≥3 points: Patient is at nutritional risk. Nutritional care plan to be set up, <3 points: Repeat screening weekly.
Nutritional Assessment

Nutritional assessment is a formal assessment of the nutritional status of a patient by a trained healthcare professional usually a dietician, and results in nutrition-related diagnosis. Once a patient is identified as at risk from the screening tools detailed, nutritional assessment should be performed. Indian Society of Critical Care Medicine practice guidelines for nutrition in critically ill patients recommend the nutritional assessment by Subjective Global Assessment (SGA). Assessment by anthropology like patient’s weight in ICU is technically difficult and may fluctuate widely due to fluid shifts during the ICU stay.

Subjective Global Assessment

It is a subjective nutritional assessment tool initially developed for post-gastrointestinal surgery patients. The SGA scale includes parameters to assess subcutaneous fat, muscle wasting, fluid retention, weight change, recent food intake, gastrointestinal symptoms, and functional capacity. Subjective Global Assessment class C includes severe malnutrition, SGA class B includes moderate malnutrition, and SGA class A includes no malnutrition. In a meta-analysis of studies of use of SGA in critically ill patients, SGA was more favorable than other assessment tools and SGA grade B and C had poor outcomes. Subjective Global Assessment is simple and easy to assess at the bedside and is cost-effective also. The main limitations of SGA were that severity of illness were not included, assessment of weight and food history in critically ill patients was difficult, changes in SGA grade takes a long time usually many days.

Besides the subjective assessment, it is also important to assess the gastrointestinal tract with gastric residual volumes to assess the nutritional status in critically ill patients.

Other methods studied were use of computed tomography (CT) scan to assess the muscle mass, as CT scan is cumbersome use of ultrasonography assessment of quadriceps muscle thickness has been studied. Ultrasonography is a simple, noninvasive, bedside tool to assess muscle mass. It can be performed serially and detect short-term changes. A prospective study by Rodrigues et al. assessed quadriceps and rectus femoris muscle thickness using ultrasonography and the reduction in muscle mass was correlated with severe malnutrition. Ultrasonographic assessment of muscle mass needs further validation and is a useful future tool.

Bioelectrical impedance is another tool used to measure fat free mass; however, the fluid electrolyte imbalance in critically ill patients affects the measurements taken.

Practical Implications of Nutritional Assessment in Critically Ill Patients

Nutrition assessment and prescription in critically ill patients is often ignored world over. International guidelines recommend that every patient should be screened for malnutrition within 24–48 hours of ICU admission, as many of these patients are at a risk or may have malnutrition at admission to ICU due to the underlying severity of the illness.

Malnutrition and muscle wasting set in early during the ICU stay because of the imbalance between energy and protein requirements and intake. A trained nutrition expert or a dietician is not necessary to identify patients who are, or at risk of malnutrition. Nutrition assessment starts with a good patient history and physical examination for emaciation and loss of muscle mass. But loss of muscle function may occur much before loss of muscle mass, which may go unnoticed in an obese or fluid retained critically ill patient, unless actively screened. Anthropometric measurements like patient’s weight in ICU is technically difficult and may fluctuate widely due to fluid shifts during the ICU stay.

The NUTRIC score is an easy screening tool which can be used at the bedside. If found at risk the patient should be assessed in detail by a nutritionist/dietician or by the treating clinician if nutritionist is not available. Nutritional assessment should be performed using the SGA tool. The SGA although validated in critically ill

---

**Table 4: NUTRIC score variables**

| Variable | Range    | Points |
|----------|----------|--------|
| Age      | <50      | 0      |
|          | 50 to <75 | 1      |
|          | >75      | 2      |
| APACHE II| <15      | 0      |
|          | 15 to <20 | 1      |
|          | 20–28    | 2      |
|          | >28      | 3      |
| SOFA     | <6       | 0      |
|          | 6 to <10 | 1      |
|          | >10      | 2      |
| Number of comorbidities | 0–1 | 0 |
|          | >2       | 1      |
| Days from hospital to ICU admission | 0 to <1 | 0 |
|          | >1       | 1      |
| IL-6     | 0 to <400| 0      |
|          | >400     | 1      |

**Table 5: NUTRIC scoring system: if IL-6 available**

| Sum of points | Category | Explanation |
|---------------|----------|-------------|
| 6–10          | High score | Associated with worse clinical outcomes (mortality, ventilation). |
|               |          | These patients are the most likely to benefit from aggressive nutrition therapy. |
| 0–5           | Low score | These patients have a low malnutrition risk. |

**Table 6: NUTRIC scoring system: if no IL-6 available**

| Sum of points | Category | Explanation |
|---------------|----------|-------------|
| 5–9           | High score | Associated with worse clinical outcomes (mortality, ventilation). |
|               |          | These patients are the most likely to benefit from aggressive nutrition therapy. |
| 0–4           | Low score | These patients have a low malnutrition risk. |

*It is acceptable to not include IL-6 data when it is not routinely available; it was shown to contribute very little to the overall prediction of the NUTRIC score.*

---
patients has its limitations; to obtain the necessary anthropometric measurements and muscle function assessment in a sedated patient may be near impossible.

Body composition assessment using ultrasound, computed tomography, and bioimpedance are relatively new tools and technically limited in critically ill patients, currently being used only for research.

Nutrition screening and assessment should be a continuous process for all hospitalized patients so as to intervene early with necessary protein and energy supplementation.

**Conclusion**

Patients in ICU are at a high risk of malnutrition and poor outcomes related to it. Assessment of nutritional status is not an easy process. There is no gold standard assessment score or tool available for nutritional assessment. However, it is important to assess the critically ill patients using the best tools available and institute optimal nutrition to these patients. Further research is warranted for a better validated screening tool for nutrition assessment in the critically ill.
