Abstract

The endemic Indian white shrimp (*Penaeus indicus*) is an economically important shrimp species, distributed in the Indo-West Pacific region. Knowledge of gut microbial composition helps in dietary interventions to ensure improved health and production. Here we analyzed V3-V4 hypervariable regions of the 16S rRNA gene to examine intestinal microbiota in the wild and farmed *P. indicus*. The study revealed *Proteobacteria, Fusobacteria, Tenericutes*, and *Bacteroidetes*, were the dominant phyla in both the groups; though the differences in relative abundance were evident. The dominant genera in case of the wild group were *Photobacterium* (29.5%) followed by *Propionigenium* (13.9%), *Hypnocyclicus* (13.7%) and *Vibrio* (11.1%); while *Vibrio* (46.5%), *Catenococcus* (14%), *Propionigenium* (10.3%) and *Photobacterium* (8.7%) were dominant in the farmed group. The results of the study suggest the role of environment on the relative abundance of gut bacteria. This is the first report characterizing gut microbial diversity in *P. indicus*, which can be used to understand the role of gut microbiota in health, nutrition, reproduction, and growth.

Introduction

Gut microbiota is known to play an important role in host development, health and growth of various terrestrial and aquatic animals (Nelson et al. 2013; Kho and Lal 2018; Li et al. 2018; Butt and Volkoff 2019). Continuous efforts are being made to enhance the knowledge of microbiota-host interactions in aquatic animals. The gut microbiota of commercially important shrimps, *Penaeus merguiensis* (Oxley et al. 2002), *P. chinensis* (Liu et al. 2011) and *P. penicillatus* (Wang et al. 2014), have been reported from wild and farmed environments using traditional culture-dependent approaches. Recently, high throughput sequencing approach was applied to understand the gut microbiota of *P. vannamei* (Chen et al. 2017; Cornejo et al. 2017; Zeng et al. 2017; Li et al. 2018; Md-Zoqrat et al. 2018; Fan and Li 2019; Fan et al. 2019; Gao et al. 2019), *P. monodon* (Chaiyapechara et al. 2012; Rungrassamee et al. 2013, 2014, 2016) and *P. stylirostris* (Cardona et al. 2016) from farmed, wild, diseased and grown under different environmental conditions.

The Indian white shrimp (*P. indicus*) is endemic to Indo-West Pacific region, and it is an economically important shrimp species for aquaculture in India and the Middle East (CIBA Annual report 2017, Sajeela et al. 2019). *P. indicus* was the primary shrimp species for aquaculture in the region before adopting *P. monodon* (Black tiger shrimp) for its higher productivity (CIBA Annual report 2017) followed by specific pathogen-free (SPF) and selectively bred *P. vannamei* (Pacific white shrimp) since 2010 (Remany et al. 2010). At present, shrimp farming is dominated by a single species, *P. vannamei*. Species diversification is essential for sustainable farming activity (Metian et al. 2020); hence, attempts are underway in India to revive the culture of *P. indicus* through improved emphasis on captive breeding, seed production and intensive farming. The large-scale demonstration of *P. indicus* farming has been successfully conducted using hatchery-produced seeds in the country (CIBA Annual report 2017).
Specific gut microbiota has been reported to influence the reproductive fitness of the captive broodstock of black rhino (Antwis et al. 2019), indicating the role of microbiota in reproductive activities. Identification of such biomarkers helps in developing breeding plans and production of healthy offspring in penaeid shrimps. The early stages of larval development face challenges with bacterial infections leading to mortalities in hatcheries and grow-out farms (Vandenberghe et al. 1999; Zhou et al. 2012). Following the regulatory restrictions on the use of undesired pharmacologically active substances in aquaculture, the use of beneficial microbes to manipulate the intestinal microbiota was suggested (Nayak 2010). Hence, maintaining the right balance of gut microbiota is crucial for the overall health of the host. Presently, there are no reports on the gut microbiota of *P. indicus*. Analysis of the gut microbiome of *P. indicus* (wild and farmed) may provide crucial information on the microbial diversity and composition.

With the emergence of next-generation sequencing (NGS) technologies, 16S rRNA high throughput sequencing has become more comprehensive culture-independent approach to study gut microbiota (Tarnecki et al. 2017). In this study, we have used 16S rRNA high throughput sequencing to study the composition of gut bacterial communities of *P. indicus*. This study will be the preliminary understanding for further deeper investigations.

**Materials And Methods**

**2.1. Shrimp and intestinal sample collection**

*P. indicus* (n = 15, 12.83 ± 1.37 g) were collected from the ponds of domestication and captive breeding program facility at the Muttukadu Experimental Station of ICAR-Central Institute of Brackishwater Aquaculture, reared at a stocking density of 30/ m², fed with an artificial diet containing 35% protein. Wild *P. indicus* (n = 15, 13.11 ± 1.82 g) were collected from the Bay of Bengal near Kalpakkam, Chennai, Tamil Nadu (12o30'48.5" N 80o09'54.6" E) region in June 2019. Both the groups were shifted to the laboratory and maintained in seawater (35 ppt) for 24h without feeding. Shrimps with empty gut were washed thoroughly in sterile seawater, and the surface was disinfected with 70% alcohol and the whole intestine was aseptically removed and used for DNA extraction.

**2.2. DNA Extraction, library preparation and sequencing**

Intestine from five shrimp was pooled to avoid individual bias. Genomic DNA from the intestine samples was extracted using the QIAamp DNA stool mini kit (Qiagen, Germany) according to the manufacturer’s protocol. The DNA concentration and purity were determined using NanoDrop ND-1000 spectrophotometer (Thermo Scientific, USA). Three samples each from wild and farmed shrimp were subjected for PCR amplification and next-generation sequencing (Eurofins Genomics and Bioinformatics Laboratory, India). The 16S rRNA V3-V4 hypervariable region was targeted using primers 16S F GCCTACGGGNGGCWGCAG and 16S R ACTACHVGGGTATCTAATCC to profile bacterial communities. The amplicon libraries were prepared using the Nextera XT index kit (Illumina Inc. USA) as per metagenomic sequencing library preparation protocol and sequenced using Illumina MiSeq platform.
2.3. Data analysis

The raw sequences were processed using MOTHUR pipeline (v. 1.42) (Schloss et al. 2009) to filter reads, create contigs; reduce noise as per standard MiSeq procedure. Sequences were aligned, clustered and identified taxonomically with SILVA database (http://arb-silva.de) release 132. Chimera.vsearch option was used to identify and remove chimeras. Sequences with 97% identity threshold were classified into operational taxonomic units (OTUs) at genetic distances of 0.03. Taxonomy was assigned by comparing to the reference database (Schloss et al. 2009; Wang et al. 2007) and aligned using the align.seqs command in MOTHUR. Sequences were rarefied before calculation of alpha and beta diversity statistics. Alpha diversity indexes were calculated from rarefied samples using calculators for richness and diversity indices of the bacterial community (i.e., sobs, Chao, Shannon, Simpson, and ACE). Venn diagram was prepared using a web-based tool, interactiVenn (Heberle et al. 2015). Non-parametric t-test was carried out using linear discriminant analysis (LEfSe) to determine the significantly differing OTU's between the groups. The data output was subjected to detailed statistical and meta-analysis using an online tool MicrobiomeAnalyst (Dhariwal et al. 2017) for visualization.

Results

3.1. Characteristics of 16s rRNA sequencing

Microbiota of *P. indicus* was analyzed by sequencing 16S rRNA gene (V3-V4 hypervariable regions) using Illumina MiSeq platform and was processed using MOTHUR pipeline. After filtering and removal of chimera and undesirable sequences, a total of 598214 high-quality reads were obtained from six samples with an average of 99702 reads, ranging from 67571 to 114392. A total of 4502 OTU's were obtained at a sequence similarity of 97%. The rarefaction curves for the OTU's detected in this study showed that the quality of observed species increased with the depth of sequencing (Figure S1). Good's coverage estimator for all samples was > 99.1%, indicating the maximum coverage and the samples were represented sufficiently. Detected bacteria in both the samples (wild and farmed) were classified into 31 phyla, 72 classes, 187 orders, 324 family and 588 genera. 0.08 % of the bacteria in farmed and 0.14% in wild samples were unclassified.

3.2. Diversity analysis of microbiota in wild and aquacultured *P. indicus*

Diversity indices provide crucial quantitative information about rarity and commonness of species which helps to understand community structure. We measured α-diversity (Chao 1, ACE, Shannon and Simpson) indices of wild-caught and farmed *P. indicus* microbiota. The α-diversity indices showed significant differences between the wild and farmed group. The wild samples showed increased richness (Chao and ACE) and evenness (Shannon, Simpson) compared to farmed group (Fig. 1). There were no significant differences in the homogeneity (within-group similarity) and composition of microbiota between wild and farmed shrimp.
3.3. Comparison of gut microbiota between wild and aquacultured P. indicus

The most abundant phylum commonly present in *P. indicus* from wild and aquaculture origin were represented mainly by *Proteobacteria* and *Fusobacteria* while *Tenericutes, Firmicutes, Bacteroidetes, Planctomycetes* and *Cyanobacteria* were in lesser abundance (Fig. 2a). At generic level, *Vibrio, Photobacterium, Catenococcus, Propionigenium* and *Hypnocyclicus* were highly abundant (Fig. 2b) which formed the core microbiota. The shared taxa in both the groups may be considered as core gut microbiota and 329 OTUs were shared between wild and aquacultured shrimp (Fig. 3), while 71 were unique to wild and 30 were unique to farmed group.

3.4. Composition of microbial communities in wild and aquacultured P. indicus

The relative abundance data of farmed *P. indicus* showed differences from that of wild and Fig. 4a show the relative abundance of top ten phyla. In wild shrimp the five most abundant phyla (> 90%) were *Proteobacteria* (58.64%), *Fusobacteria* (27.75%), *Bacteroidetes* (4.57%), *Planctomycetes* (2.23%) and *Epsilonbacteraeota* (1.90%); whereas in farmed shrimp, the five most abundant phyla (> 90%) were *Proteobacteria* (77.27%), *Fusobacteria* (12.88%), *Tenericutes* (5.38%), *Firmicutes* (1.79%) and *Cyanobacteria* (1.16%).

At genus level, the wild *P. indicus* microbiota mainly consisted of *Photobacterium* (29.5%), *Propionigenium* (13.9%), *Hypnocyclicus* (13.7%), *Vibrio* (11.1%), *Catenococcus* (9.9%) and *Tenacibaculum* (3.3%); whereas *Vibrio* (46.5%), *Catenococcus* (14.0%), *Propionigenium* (10.3%), *Photobacterium* (8.7%), *Candidatus_Hepatoplasma* (5.3%), *Gammaproteobacteria_unclassified* (4.3%) and *Hypnocyclicus* (2.5%) were the most abundant genus in aquacultured shrimp (Fig. 4b).

Linear discriminant analysis effect size (LEfSe) was performed to identify the specific taxa significantly varied in abundance in with wild or farmed shrimp. The significant differences were observed in the phylum *Proteobacteria, Tenericutes, Firmicutes, Kiritimatiellaeota, Planctomycetes, Dadabacteria, Chlamydiaceae*. In total, 30 genera, varying significantly were identified with LDA scores > 3 (Figure S2). Genus *Vibrio* was significantly associated with the farmed group, while *Photobacterium* was significantly associated with the wild group.

**Discussion**

Information on gut microbial diversity of a commercially farmed seafood species will help in devising suitable intervention strategies for enhanced health, growth and production. The gut microbiota is an evolving system (Li et al. 2017) and the abundance and species diversity will play a significant role in host development, physiology, immune system and growth (Ramírez et al. 2017, 2017a). Considering the lack of data, wild and farmed *P. indicus* were analyzed for gut microbiota. This is the first characterization
of gut microbiota in Indian white shrimp (P. indicus) employing 16S rRNA high-throughput sequencing. The culture-independent methods are more reliable to characterize the bacterial diversity than the culture dependent methods, as majority (98–99 %) of the bacteria are unculturable and those obtained by culture-based methods are not a true representative of the bacterial diversity (Ringo et al. 2016; Qiao et al. 2017; Suo et al. 2017).

The results obtained in this study were consistent with other aquatic organisms in having a sizeable bacterial diversity (Ramírez et al. 2017; Wu et al. 2012). The Good’s coverage was > 99.1%, suggesting the maximum coverage and complete identification of bacterial communities in all the samples.

The core gut microbiota, which forms > 90% of the bacterial diversity in P. indicus from wild were mainly classified into Proteobacteria, Fusobacteria, Bacteroidetes, Planctomycetes and Epsilonbacteraeota at the phylum level. At the same time, farmed shrimp have a core microbiota comprising of Proteobacteria, Fusobacteria, Tenericutes, Firmicutes and Cyanobacteria. Abundance of Proteobacteria observed in the present study was consistent with the reported results from other important penaeid shrimps P. vannamei (Chen et al. 2017; Cornejo et al. 2017; Zeng et al. 2017; Li et al. 2018; Md-Zoqratt et al. 2018; Fan and Li 2019; Fan et al. 2019; Gao et al. 2019), P. monodon (Chaiyapechara et al. 2012; Rungrassamee et al. 2013, 2014, 2016) and P. stylirostris (Cardona et al. 2016) and other aquatic organisms (Roeselers et al. 2011; Wu et al. 2012). Several studies in P. vannamei shows that Proteobacteria remains dominant, despite dietary modifications and physiological stress (Li et al. 2018). Though prevalence was similar, variation in the abundance of different phyla was observed between the shrimp groups. The microbiota will change according to the changes accompanying host development, diet, stress, and disease status and host phylogeny (Cardona et al. 2016; Yan et al. 2016). The artificial environment in farming system having different parameters from that of the natural environment might have led to the variation in the abundance of gut microbiota. The wild P. indicus mainly feed on gastropods, bivalves, crustaceans, polychaete, plant tissues, detritus etc. While, the aquacultured shrimp were fed with a formulated feed containing 35% proteins. Hence, the observed differences in the abundance of gut microbiota in the present study might be attributed to the change in environment, density of the animals and the diet.

Although Proteobacteria were abundant in both the group of shrimps, they were differentially distributed at the genus level. For example, the genus Vibrio is dominant (46.5%) in farmed shrimp, while the wild harbored 11.1%. In a similar study, Rungrassamee et al. (2014) reported a progressive increase in the abundance of Vibrio spp until 90 days (32.9%) of observation in farm-reared P. monodon suggesting the role of environment and diet on the load of vibrios in the gut. On the contrary, a higher vibrio load in the wild (20%) compared to the farmed (15.1%) was reported in P. vannamei (Cardona et al. 2016). Rungrassamee et al. (2016) reported that, P. vannamei was able to restore normal gut microbiota and resist V. harveyi challenge compared to P. monodon. Vibrios are opportunistic pathogens of shrimps, which can cause up to 100% mortality (Liu et al. 2016). However, Zheng et al. (2017) demonstrated that all the dominating vibrio in the diseased shrimp were not pathogenic. Recently, Garibay-Valdez et al. (2018) reported that Vibrio spp maintain symbiotic relationship with host and gut microbiota in addition to modulating host signaling proteins, activate defense system and improve immune response like
prophenoloxidase and superoxide dismutase activities (Ma et al. 2018; Qi et al. 2017; Velázquez et al. 2019). Further, *Vibrios* like *V. gazogenes* have been reported to confer resistance to bacterial infection suggesting their potential probiotic activity (Thompson et al. 2010). The higher abundance of *Vibrio* in healthy farmed shrimp may involve in these critical activities.

Followed by *Vibrio*, the genus *Photobacterium* was dominant among *Proteobacteria* and was abundant in gut of wild (29.5%) compared to cultured (8.7%) shrimp. *Photobacterium* is characterized as free-living marine commensals present in the gut of several marine organisms and reported as the indigenous bacterial population (Rungrassamee et al. 2014). Twenty species have been reported in the genus (Urbanzcyk et al. 2011) and *Photobacterium damsela* sub *sp. damsela* is reported to be pathogenic to several marine finfish (Liu et al. 2016). Recently, Wang et al. (2019) suggested that *Photobacterium* play various roles in the health of *P. vannamei*. However, few reported the role of *P. damsela* sub *sp. Damsela* in the black gill of *P. monodon* (Vaseeharan et al. 2007) and a symptom similar to AHPND in *Exopalaemon carinicauda* (Liu et al. 2016). The presence of *Vibrio* and *Photobacterium* in both wild and aquacultured shrimp gut indicates that they might be the common residents of *P. indicus* microbiota. Further efforts are required to study the association of these bacteria at different growth stages, and the effect of their dynamics on the health and metabolic functions.

We observed an abundance of *Fusobacteria* both in wild and farmed shrimp gut, and it was the second most dominant phyla; while their abundance was reportedly low in *P. vannamei* (Zhang et al. 2016) and *P. monodon* (Rungrassamee et al. 2014). Two genera, namely, *Propionigenium* and *Hypnocyclicus*, were dominant in this phylum, though their role in shrimp gut largely remains unknown. However, in a recent study, *Propionigenium* was suggested to play an essential role in limiting the WSSV infection in *P. vannamei* (Wang et al. 2019). Since our study reported an abundance of *Fusobacteria*, further investigation on their possible role in disease resistance will be of considerable significance to the aquaculture.

The phylum *Bacteroidetes* are known to improve the metabolism of polysaccharides, proteins, and other substances and enhance nutrient-utilization (Bäckhed et al. 2004) and promote the development of immune system (Hooper 2004). Significantly, lower abundance of these microbes in cultured animals (0.41%) compared to the wild (4.57%) suggest the possible opportunity for their inclusion in the dietary interventions for improved health and production in commercial shrimp operations. Though the pathogenic nature of these microbes in shrimp is not known, few reported the possible role in skin necrosis of marine fishes (Småge et al. 2016; Pérez et al. 2017; Frisch et al. 2018). Similar to previous observations (Cornejo et al. 2017; Zeng et al. 2017) the phylum *Tenericutes* were abundant (5.38%) in cultured shrimp compared to that of wild (0.18%). The abundance of genus *Candidatus_Hepatoplasma* in *Tenericutes* is correlated with the non-availability of food in ponds and suggested to play a role in host adaption to hunger situations (Fraune and Zimmer 2008; Wei et al. 2019). Additionally, several other phyla in low abundance may have a different role in the normal physiological function of the shrimp.
Understanding the gut microbial profile has implications in aquaculture, and it is evident that gut microbiota largely depends on host phylogeny and diet. Maintaining near-natural gut microbiota has several advantages, and it is crucial for dietary alterations in commercial aquaculture practices. Adoption of beneficial microbes based on these studies could aid in sustainable development and improved productivity. The presently practiced dietary interventions through the application of probiotics, prebiotics, immunostimulants, antimicrobials etc. for enhanced health and production need to be evaluated, given their impact on gut microbial diversity for their practical utility.

Conclusion

This is the first report on the gut microbiota of Indian white shrimp, *P. indicus*, employing culture-independent high throughput sequencing. The gut microbial profiles of wild-caught and farmed shrimp showed similarity in prevalence and differences in abundance. The results indicate the presence of possible host-associated resident bacterial populations while environment playing an essential role in differences in their abundance. However, *P. indicus* is distributed all along the coasts of Indian subcontinent and the inclusion of samples from all locations will enhance the resolution of gut microbiota of the species. Further studies on the gut microbiota at different growth stages and health status will help in devising intervention strategies for effective gut microbial modulations.

**Figures**
Comparison of alpha diversity indexes between wild and aquacultured Indian white shrimp (Penaeus indicus). Diversity in the gut bacterial community was measured using Chao-1, Ace, Shannon, Simpson, Fisher indices, which reflects richness and evenness of the samples.
Figure 2

The core gut microbiota of P. indicus at phylum (A) and genus (B) level identified by MicrobiomeAnalyst using the parameters sample prevalence (20%) and relative abundance (0.2%).

Figure 3

Venn diagram showing the number of OTUs that were unique or shared between wild and aquacultured shrimp.
**Figure 4**

Relative abundance of top 10 OTUs at the phylum (A) and genus (B) levels in the gut microbiota from wild and aquaculture P. indicus. The relative abundance was calculated based on taxonomy assignment using the Silva database.
