Technische Universität Graz, Petersgasse 16, A-8010 Graz, Austria

We study the single-particle properties of quarter-filled ladder systems such as α'-NaV_2O_5 by means of a recently developed generalization of the variational cluster perturbation theory to extended Hubbard models. We find a homogeneous antiferromagnetic insulating phase for nearest-neighbor repulsions smaller than a critical value, without any metallic phase for small repulsions. Different from C-DMFT and LDA considerations, the inclusion of diagonal hopping within a ladder has little effect on the bonding bands, while flattening and shifting the antibonding bands. In the low-temperature charge-ordered phase, the spectrum depends on whether the ordering is driven by the Coulomb repulsion or by the coupling to a static lattice distortion. The small change of the experimentally observed gap upon charge ordering implies that the lattice coupling plays an important role in this ordering. Inter-ladder coupling is straightforward to include within our method. We show that it has only a minor effect on the spectral function. The numerically calculated spectra show good agreement with experimental angle-resolved photo-emission data.

I. INTRODUCTION

In recent years low-dimensional strongly-correlated systems have been the subject of many experimental and theoretical studies due to their fascinating properties such as the occurrence of ordered patterns of the ion charges. A compound in this class of materials is the low-dimensional vanadium bronze α'-NaV_2O_5. Although known for many years, it has attracted considerable attention in recent years because of a very interesting low-temperature phase. The compound exhibits a spin-Peierls-like transition at T_c ≈ 35 K accompanied by the opening of a spin gap. At the same or slightly higher temperature charge ordering takes place. Different from the first X-ray investigations, recent studies at room temperature showed a disordered state with equivalent valence 4.5 for all vanadium ions. Below the phase transition point, NMR-studies gave two different valences for the ions, a clear evidence for the formation of a charge-order pattern below T_c. Since one d_{xy} electron is shared by two V sites in a V-O-V rung, the ordering occurs as a static charge disproportion δ between the V ions, yielding charges 4.5 ± δ with a zig-zag pattern of δ's. Since the crystal environment of the vanadium ions is asymmetric, the d_{xy} electrons are coupled to the lattice via a strong Holstein-like electron-phonon interaction. This results in a static lattice distortion below the charge ordering transition temperature, where the ion displacements from their positions in the high-temperature phase is of the order of 0.05 Å as observed in X-ray diffraction experiments.

Although the crystal structure of α'-NaV_2O_5 is composed of nearly decoupled two-dimensional layers that consist of coupled two-leg ladders, spin-susceptibility measurements revealed that the system can be reasonably well described by a one-dimensional Heisenberg model. This behavior could be explained by realizing that the molecular-orbital state on a rung occupied by one electron is a key element of the electronic structure, yielding quasi 1D magnetic exchange couplings. In addition angle-resolved photo-emission spectroscopy (ARPES), performed in the disordered high-temperature phase showed quasi 1D band dispersions of the vanadium 3d bands and it was argued that spin-charge separation should be present in this system.

Previous studies revealed that the electron-phonon coupling is very important for the phase transition in quarter-filled ladder compounds. For this reason we study a model Hamiltonian that includes the coupling of the d_{xy} electrons to the lattice. The relevant parameters for the study of lattice effects can be obtained from experiments (phonon frequencies), and from first-principle calculations (lattice force constants and electron-phonon coupling).

Static and dynamic properties of quarter-filled ladder compounds without coupling to the lattice have been studied intensively in the past using different methods like mean-field approaches, exact diagonalization (ED) of small clusters, cluster dynamical mean-field theory (C-DMFT), and bosonization and renormalization-group techniques. Recently the influence of the lattice coupling on the charge-ordering transition was investigated by employing ED methods.

In this paper we study the single-particle spectral function of the compound α'-NaV_2O_5, which can be directly related to the ARPES experiments, by applying the recently proposed variational cluster perturbation theory (V-CPT). This method is a combination of the cluster perturbation theory and the self-energy functional approach (SFA) which provides results for the infinite lattice and allows to study symmetry-broken phases. It was used with success for the investigation of the magnetic ground-state properties of the two-dimensional Hubbard model. For Hamiltonians including offsite
Coulomb interactions an extension of this theory has been developed\textsuperscript{22} which turned out to give very accurate results for the one and two-dimensional extended Hubbard model.

The paper is organized as follows. In Sec. II we introduce the model Hamiltonian and give a short description of the V-CPT method. Sec. III and Sec. IV includes our results for single and coupled ladders, respectively, and we finally draw our conclusions in Sec. V.

II. MODEL AND METHOD

On a microscopic level, α′-NaV$_2$O$_5$ can be described by an extended Hubbard model (EHM). In order to take into account lattice effects we further extend this well-known model by a Holstein-like electron-phonon coupling, which a recent LDA study\textsuperscript{20} showed to be especially important, yielding the model

\[ H = H_{\text{EHM}} + H_1 + H_{c-1}, \]  

with $H_{\text{EHM}}$ the EHM Hamiltonian, $H_1$ the contribution of the lattice, and $H_{c-1}$ the Holstein coupling. These terms are given by

\[ H_{\text{EHM}} = - \sum_{\langle ij \rangle, \sigma} t_{ij} \left( c_{i \sigma}^\dagger c_{j \sigma} + \text{H.c.} \right) \]

\[ + U \sum_i n_{i \uparrow} n_{i \downarrow} + \sum_{\langle ij \rangle} V_{ij} n_i n_j, \]  

\[ H_1 = \kappa \sum_i z_i^2, \]

\[ H_{c-1} = - C \sum_i z_i n_i, \]

where $\langle ij \rangle$ connects nearest-neighbor bonds, and $t_{ij}$ is the corresponding hopping matrix element. In Fig. 1 the lattice structure and the hopping processes used in this study are shown. The most commonly used set for these matrix elements is $t_a = 0.38$ eV, $t_b = 0.18$ eV, and $t_{xy} = 0.012$ eV, and was obtained by fitting the LDA bands.\textsuperscript{19} A recent study\textsuperscript{22} gave similar parameter values. By including the additional hopping term $t_d$ in a massive downfolding procedure, Mazurenko et al.\textsuperscript{22} found similar values for $t_a$ and $t_{xy}$, but the values $t_b = 0.084$ and $t_d = 0.083$ differ considerably from previous studies. In the present study we set $t_a$ as the energy unit and fix $t_b = 0.5$, except for Sec. III C where we study the spectral function including the hopping term $t_d$. The on-site Coulomb interaction is set to $U = 8$ throughout the paper, in accordance with band-structure calculations\textsuperscript{20} and the inter-site Coulomb interaction $V_{ij}$ is treated as a free parameter of the system, since the determination of a proper value within first-principle calculations is very difficult.

The lattice distortions are given in units of 0.05 Å, since the ion displacements in the ordered phase are of this order of magnitude. The electron-phonon coupling $C$ and the lattice rigidity $\kappa$ were determined by first-principle calculations\textsuperscript{22} yielding $C = 0.35$ and $\kappa = 0.125$ in these units. We restrict our investigations to static distortions and neglect dynamical phonon effects, similar to parts of Ref.\textsuperscript{17}. Moreover, as discussed below, we use a staggered zig-zag configuration for the $z_i$, as observed experimentally\textsuperscript{22}.

The method we use in this paper for the calculation of the single-particle spectrum is the variational cluster perturbation theory for an EHM.\textsuperscript{22} The main idea is to decouple the lattice into clusters of finite size as depicted in Fig. 2 yielding the Hamiltonian

\[ H = \sum_R \left[ H_0^{(c)}(R) + H_1(R) \right] + \sum_{R, R'} H_0^{(i)}(R, R'), \]  

where $R$ denotes the individual clusters. The first sum consists of decoupled intra-cluster Hamiltonians with interaction part $H_1(R)$, and the second sum gives the coupling between clusters, which must be of single-particle type and is of the general form

\[ H_0^{(i)}(R, R') = \sum_{\sigma, \sigma'} t_{\sigma, \sigma'}^{R, R'} c_{\sigma, R}^\dagger c_{\sigma', R'}. \]  

The indices $a$ and $b$ are orbital indices within a cluster.

In the case of the EHM this decoupling into clusters yielding Eq. (3) cannot be done in a straightforward way, since the Coulomb interaction on the decoupled bonds is
of two-particle type. In order to get a Hamiltonian of the form Eq. (3) it is necessary to do a mean-field decoupling of the Coulomb-interaction terms on inter-cluster bonds, which is described in detail in Ref. 34. The coupling of the clusters is then again of single-particle type, Eq. (4), but in addition this mean-field approximation introduces onsite potentials $\lambda_i$ on the cluster boundary, which correspond to the average electronic densities on site $i$ of the cluster boundary. Let us stress at this point that the $\lambda_i$ are not variational parameters in the sense of V-CPT but external parameters to the Hamiltonian Eq. (3) in its mean-field decoupled form, entering term $H_0^{(c)}$. After the mean-field decoupling of inter-cluster bonds, we can apply the V-CPT to the Hamiltonian Eq. (3). Obviously the Hamiltonian is invariant under the transformation

$$H_0^{(c)}(R) \rightarrow H_0^{(c)}(R) + O(R),$$

$$H_0^{(i)}(R, R') \rightarrow H_0^{(i)}(R, R') - \delta_{R, R'} O(R),$$

(5)

with an arbitrary single-particle operator

$$O(R) = \sum_{a,b} \Delta_{a,b} c_{a,R}^\dagger c_{b, R}.\quad (6)$$

This transformation allows the study of symmetry-broken phases by the inclusion of fictitious symmetry-breaking fields, which do not change the overall Hamiltonian, Eq. (3), but instead just rearrange it. They are therefore different in character from the external parameters to the Hamiltonian Eq. (3), but instead just rearrange it.

Finding the minimum in the grand potential is equivalent to a self-consistent solution for the $\lambda_i$, as shown in the appendix of Ref. 34.

In practice we used the following procedure. For a given value of the $\lambda_i$ one has to find the stationary point of $\Omega(\Delta, \lambda_i)$ with respect to $\Delta$, yielding a function $\Omega = \Omega(\lambda_i)$. The proper value of the external parameters $\lambda_i$ is then given by the minimum of this function.

In Sec. III D we study the effect of the lattice distortions $z_i$, and the optimal distortions are determined by the minimum ground-state energy. From a technical point of view these distortions are treated on the same level as the mean-field parameters $\lambda_i$, since they are external parameters to the Hamiltonian, Eq. (4), as well. In this case on has a function $\Omega(\Delta, \lambda_i, z_i)$. Again, for each pair $\lambda_i, z_i$ one looks for the stationary point with respect to $\Delta$, and the proper choice of $\lambda_i$ and $z_i$ is then given by the minimum of the function $\Omega(\lambda_i, z_i)$.

The single-particle Green’s function is then calculated by

$$G_q(\omega) = \left[G_0(\omega) - T_q\right]^{-1},\quad (8)$$

with the Fourier-transformed matrix elements $T_{q,a,b}$. After applying a residual Fourier transformation one finally obtains the fully momentum-dependent Green’s function $G(k, \omega)$ for the infinite size system. Note that the external parameters $(\lambda_i, z_i)$ are only present in the calculation of $G_0(\omega)$, whereas the variational parameters $\Delta$ also enter $T_q$, see Eqs. (11,10).

Since calculations are not done at half filling, the chemical potential $\mu$ is not known a priori. However, the knowledge of $\mu$ is important for the evaluation of the grand potential, as discussed above. One can calculate $\mu$
from the condition
\[ n = \frac{2}{L} \sum_k \int_{-\infty}^{\mu} d\omega A(k, \omega), \]  
(9)
where the spectral function \( A(k, \omega) \) is given by
\[ A(k, \omega) = -\frac{1}{\pi} \text{Im} G(k, \omega + i\eta) \]  
(10)
and \( \eta \) is a small Lorentzian broadening. This amounts to a self-consistent procedure, since for the calculation of \( \mu \) the Green’s function \( G(k, \omega) \) is needed, and for the determination of \( \mu(k, \omega) \) one has to know \( \mu \). This cycle can be avoided as follows. One can infer the chemical potential directly from the energies of the excited states obtained by the ED. An approximate value for the chemical potential is given by
\[ \mu_{\text{ED}} = \frac{E^{\text{IPES}}_{\text{min}} + E^{\text{PES}}_{\text{max}}}{2}, \]  
(11)
with \( E^{\text{IPES}}_{\text{min}} \) the minimal energy of inverse-photo-emission (IPES) states and \( E^{\text{PES}}_{\text{max}} \) the maximum energy of photo-emission (PES) states. This value only weakly depends on the mean-field and variational parameters. As discussed below, in all our calculations we found a well-established gap between the PES and IPES states yielding a constant density \( n \) in a reasonably large neighborhood of the physical chemical potential \( \mu \), in agreement with quantum Monte Carlo calculations. Therefore \( \mu_{\text{ED}} \) gives a reasonable approximation for our calculations.

For the details of this method and the calculation of the grand potential we refer the reader to Refs. and references therein.

III. RESULTS FOR SINGLE LADDERS

A. Critical coupling

We start our investigations with decoupled ladders, i.e., \( t_{xy} = 0 \) and \( V_{xy} = 0 \) (Fig.1). Before we turn to the spectral function, we study the charge-ordering transition as a function of \( V = V_a = V_b \). Let us first look on the effect of the mean-field decoupling of the non-local Coulomb interactions across cluster boundaries as described in Sec. We for this purpose consider the EHM without coupling to the lattice in the limit of exactly one electron per rung and \( t_b = 0 \), i.e., without hopping between rungs. In mean-field approximation this case results in a second-order phase transition between a disordered state and a zig-zag ordered state at a critical interaction of \( V^{\text{MF}} = 1.0 \). On the other hand this case is exactly solvable by a mapping to an Ising model in a transverse field yielding a critical interaction of \( V_c^{\text{exact}} = 2.0 \). Thus we expect strong mean-field effects, since in this special limit we found \( V_c^{\text{exact}} = 2V^{\text{MF}} \). Since it can be assumed that a finite value of the hopping between adjacent rungs \( t_b \) weakens the charge ordering, the actual critical value \( V_c \) is presumably located slightly above 2.0 when \( t_b \) is included.

For single ladders at quarter filling one has only two different values for the mean-field parameters \( \lambda_i \), namely \( \lambda_A \) on sublattice \( A \) and \( \lambda_B \) on sublattice \( B \), which correspond to the left and right side of the rung on the cluster boundary, respectively, see Fig.1. In order to reduce the number of mean-field parameters, we set \( \lambda_A = \langle n \rangle + \delta \) and \( \lambda_B = \langle n \rangle - \delta \), with the average density fixed to \( \langle n \rangle = 0.5 \). This yields only one mean-field parameter \( \delta \) instead of two parameters, \( \lambda_A \) and \( \lambda_B \).

For second-order phase transitions it can in addition be important to rearrange the Hamiltonian by means of a fictitious staggered chemical potential as a variational parameter. This field is included by adding and substracting (Eq. (9)) the single-particle operator \( \mathcal{O}(R) \), Eq. (6), with
\[ \Delta_{a,b} = \epsilon \delta_{a,b} Q R a, \]  
(12)
where \( \epsilon \) denotes the variational parameter, \( r_a \) is the lattice vector of site \( a \), \( \delta_{a,b} \) is the Kronecker-\( \delta \) for sites \( a,b \), and \( Q = (\pi, \pi) \). Initial calculations showed that in the present case the inclusion of such a field does not have any significant effect and the relative change in \( \Omega \) is at most of the order of \( 10^{-4} \). Although the staggered field Eq. (12) is the Weiss field associated with the CDW, its effect is very small, since the symmetry is already broken by the mean-field decoupling at the boundaries. We also considered a staggered chemical potential similar to Eq. (12), but which is nonzero only on the cluster boundaries. In the spirit of V-CPT this corresponds to include the mean-field parameter \( \delta \) also in the set of variational parameters \( \Delta \). Not surprisingly, the effect of this field was even smaller than for the field Eq. (12). For this reason all further calculations have been done without a staggered chemical potential.

We now discuss our results, setting \( t_b = 0.5 \). We first discuss the case without coupling to the lattice. Finite lattice coupling will be considered in Sec. In order to determine the order of the transition within the framework of V-CPT it is sufficient to calculate the grand potential \( \Omega \), Eq. (7), as a function of the mean-field parameters. Fig. shows the dependence of \( \Omega(\delta) \) on the mean-field parameter \( \delta \) calculated with a \( 6 \times 2 \) cluster as reference system. One can see that the system undergoes a continuous phase transition which is located between \( V = 1.5 \) and \( V = 1.7 \), since the minimum of \( \Omega(\delta) \) shifts from \( \delta = 0 \) to a finite value. This value for the critical interaction is considerably smaller than the above mentioned value of the analytical solution, but the agreement is much better than the result of the purely mean-field calculation, \( V^{\text{MF}} = 1.0 \).

In order to study the finite-size dependence of the critical Coulomb interaction we performed calculations on clusters of different length, and the results are depicted in Fig.3. The steps in \( V \) in our calculations were \( \Delta V = 0.01 \), which results in error bars of \( \Delta V_c = 0.005 \).
FIG. 2: Grand potential $\Omega(\delta)$ as a function of the mean-field parameter $\delta$ with a $6 \times 2$ cluster serving as reference system, and without coupling to the lattice. Upper panel: $V = 1.5$. Lower panel: $V = 1.7$.

FIG. 3: Finite-size dependence of the critical Coulomb interaction $V_c$ without lattice coupling. Error bars are due to the finite step $\Delta V = 0.01$ in the calculations. Dotted line: Linear extrapolation of the 8 and 6 rung cluster. Dashed line: Quadratic extrapolation of the 8, 6, and 4 rung cluster.

As expected, $V_c$ is strongly finite-size dependent. From Fig. 3 we can expect that for larger cluster sizes the critical interaction $V_c$ increases further and reaches the expected value of slightly above 2.0, but for a more sophisticated finite-size scaling our cluster sizes are too small. Nevertheless it is possible to study the spectral function both in the disordered and the ordered phase. Since the calculations for the $8 \times 2$ ladder are very time consuming, all single-ladder spectra presented in this paper have been determined with a $6 \times 2$ ladder as reference system.

B. Disordered phase

We start our investigations of the spectral function with the disordered high-temperature phase. Since $\alpha'$-NaV$_2$O$_5$ may be near a quantum critical point between ordered and disordered phase, we choose the nearest neighbor interaction to be slightly below the critical value. We set $V = V_a = V_b = 1.3$, $t_b = 0.5$, and we do not include diagonal hopping, i.e., $t_d = 0$. The result of this calculation is shown in Fig. 4. An additional Lorentzian broadening of $\eta = 0.1$ has been used for all spectra shown in this paper. The dashed vertical line marks $\mu_{\text{ED}}$ calculated from Eq. (11), and the dotted line denotes $\mu_{\text{CPT}}$ determined from the condition Eq. (9). For the latter quantity the sum over momentum vectors had to consist of about 80 vectors in order to get a well converged result. It is easy to see that $\mu_{\text{ED}} = 1.71$ lies exactly in the middle of the gap, whereas $\mu_{\text{CPT}} = 1.23$ is located at its lower boundary. But since there are no in-gap states both values of $\mu$ give approximately the same average density $n$, and the ground-state energy $E_0 = \Omega + \mu N$ hardly depends on whether we use $\mu_{\text{ED}}$ or $\mu_{\text{CPT}}$. These facts confirm that our approximation to use $\mu = \mu_{\text{ED}}$ as chemical potential gives correct results, and in addition the numerical effort for this procedure is much less than for the above described self-consistent determination of $\mu$. 

FIG. 4: Single-particle spectral function $A(k, \omega)$ calculated with a $6 \times 2$ cluster in the disordered phase at $V_a = V_b = 1.3$. Top panel: Momentum $k_a = 0$ perpendicular to the ladder. Bottom panel: $k_a = \pi$. The dashed line marks the chemical potential calculated by Eq. (11), the dotted line marks the result obtained from Eq. (9).
As one can easily see in Fig. 4, the spectral function exhibits a well defined gap around the chemical potential, a clear indication of insulating behavior. In order to check if the insulator is only stable above some critical inter-site Coulomb interaction, we calculated the gap \( \Delta \) at \((k_a, k_b) = (0, \pi/2)\) as a function of the intra-rung interaction \( V_a \). We studied two cases with \( V_b = 0 \) and \( V_b = V_a \), respectively, and the results are shown in Fig. 5. Note that for \( V_b = 0 \) no mean-field decoupling is needed, since there are no interaction bonds between different clusters. At \( V_a = 0 \), where both cases are equivalent, we found a finite value of the gap, \( \Delta \approx 0.55 \). We checked the finite size dependence by calculating the gap on a \( 4 \times 2 \) cluster giving \( \Delta \approx 0.59 \). By applying a linear \( 1/N_{\text{rungs}} \) extrapolation to \( N_{\text{rungs}} = \infty \) one gets \( \Delta \approx 0.47 \), indicating that the curves in Fig. 5 somewhat overestimates the value of the gap for the infinite ladder. Nevertheless we conclude from our calculations that the system is insulating already for small values of \( V_a \). This is consistent with DMRG calculations \cite{26} where for \( t_a > t_b \) a homogeneous insulating phase has been found for \( V = 0 \). The behavior of the spectral function is also in agreement with ED calculations on small clusters for \( V = 0 \), where for large enough \( t_a \) an insulating state has been found. Similar results have been obtained by Kohno \cite{25} for the \( U = \infty \) Hubbard ladder.

In the case \( V_b = 0 \), which means that there is no Coulomb interaction between adjacent rungs, we found that \( \Delta \) increases linearly with \( V_a \). For \( V_b = V_a \) the gap is slightly larger and the deviation increases with increasing \( V_a \). Here, with a \( 6 \times 2 \) cluster as reference system, the system starts to order at \( V_c \approx 1.625 \), which results in the kink in \( \Delta \) around this critical value. Note that for \( V_b = 0 \) such a phase transition is not possible.

Let us now discuss the spectral features for \( k_a = 0 \) as shown in Fig. 4. The spectral function looks very similar to that of the half-filled one-dimensional Hubbard model with a totally filled lower and an empty upper band. Different from the 1D Hubbard model the gap between these two bands is not only determined by the onsite interaction \( U \), but mainly by the intrarung interaction \( V_a \), as discussed above. At \( k = (0, 0) \) one can see signatures of spin-charge separation, where the band is split into a low energy spinon band (at approximately \( \omega - \mu \approx -1.5 \)) and a holon band at slightly higher energy (\( \omega - \mu \approx -2.0 \)). This splitting has not been seen directly in experiments, since it is small and temperature effects did not allow a high enough experimental resolution. However, by studying the temperature dependence of ARPES spectra, it was argued that subtle spectral-weight redistributions can be related to spin-charge separation. Some spectral weight can also be found at very high energies of about \( \omega - \mu \approx 8.5 \), which is close to the onsite energy \( U = 8 \) and can thus be related to doubly-occupied sites.

Infrared (IR) experiments probe transitions near the \( \Gamma \) point, that is between even \((0, 0)\) and odd \((0, \pi)\) states in the language of single ladders. From Fig. 4 one can extract an excitation energy of roughly \( 3t_a \), which is in good agreement with the experimentally found 1 eV absorption peak.

The lower and upper band disperse with period \( \pi \) indicating a doubling of the unit cell in real space, similar to the 1D Hubbard model. In order to determine the origin of this doubling we have calculated the real-space spin correlation function \( S_r = \langle S^z_r S^z_{r+1} \rangle \) within the cluster by exact diagonalization, where \( S^z_r \) and \( S^z_{r+1} \) are the \( z \)-components of a spin on the cluster boundary and on a rung with distance \( r \) to the boundary. In the upper panel of Fig. 4 this correlation function is shown for
two different paths, where the solid line is $S_c$ along one leg of the ladder, and the dashed line is $S_c$ on a zig-zag path through the ladder. Both correlation functions show clear antiferromagnetic correlations along the ladder similar to results obtained by the finite-temperature Lanczos method. By applying a fictitious symmetry-breaking magnetic field via the operator $O(R)$, Eq. (6), we can estimate whether this ordering is of long-range type or not. Similar to Ref. 25, we choose for this field

$$\Delta_{a,b} = \hbar \delta_{a,b} z_\sigma e^{iQr_a},$$  \hspace{1cm} (13)$$

where $z_\sigma$ is $\pm 1$ for spin $\uparrow, \downarrow$ in the orbitals $a,b$, $\delta_{a,b}$ is the Kronecker-$\delta$, and $h$ is the field strength. The wave vector $Q$ is set to $(0, \pi)$ yielding a staggered field along the ladder. The dependence of $\Omega$ on this fictitious field is depicted in the lower panel of Fig. 6. Similar to the one-dimensional Hubbard model at half filling, there is only one stationary point at $h = 0$, which means that the system does not show long-range antiferromagnetic order, but is rather in a paramagnetic state with short-range antiferromagnetic correlations.

The above considerations show that the system exhibits short-range antiferromagnetic spin correlations along the ladder, which can produce the doubled unit cell. Nevertheless it is also possible that the doubling of the unit cell is due to short-range charge correlations and not due to spin correlations. In order to clarify this point we calculated the spectral function at $V_a = 0$ and finite $V_a$, where no charge ordering is possible. Also in this case the periodicity of the bands with largest spectral weight is $\pi$ at $k_a = 0$ and $2\pi$ at $k_a = \pi$. This shows that below the phase transition at $V_a = 1.3$, the doubling of the unit cell is mainly due to short-range spin correlations, and charge correlations play only a minor role in this context.

When turning to $k_a = \pi$, the spectral function looks totally different. As we can easily see in Fig. 6 there is hardly any spectral weight below the chemical potential, which means that there are no occupied states in the channel $k_a = \pi$. This can be understood, because $k_a = \pi$ corresponds to an antibonding state within a rung, which has energy $2t_a$ relative to the bonding orbital and is therefore not populated in the ground state.

An obvious difference between the spectra for $k_a = 0$ and $k_a = \pi$ is that in the latter case the excitations with largest spectral weight located between $\omega \approx 3$ and $\omega \approx 4.5$ disperse with periodicity $2\pi$ instead of $\pi$. Qualitatively this can be understood as follows. When inserting a particle with $k_a = 0$, this electron will occupy a state in the bonding orbital. Since one of the two states in this orbital is already occupied, the additional particle must have opposite spin, and thus this particle is connected to the antiferromagnetic background. A particle with $k_a = \pi$ occupies a state in the antibonding orbital, and since this orbital is not occupied, both spin directions possess equal possibility. Therefore an electron with $k_a = \pi$ is not influenced by the antiferromagnetism in the ground state.

![FIG. 7: Spectral function $A(k, \omega)$ when the diagonal hopping is included, $t_a = 0.25$, $t_b = 0.25$. The Coulomb interaction was $V_a = V_b = 1.3$. The dotted line marks the chemical potential.](image)

**C. Disordered phase including diagonal hopping**

So far we have studied single ladders only with hopping parameters $t_a$ and $t_b$ and neglected additional diagonal hopping processes $t_d$, as indicated in Fig. 4. These hopping processes have been important in first-principle calculations in order to fit the LDA bands correctly. Moreover $t_d$ has been important in C-DMFT calculations in order to describe the insulating state in the disordered phase properly. In this section we study the effect of $t_d$ within the V-CPT framework.

In Fig. 7 the spectral function is shown for $V_a = V_b = 1.3$, $t_a = 0.25$ and $t_d = 0.25$, where the hopping parameters $V_a$ and $V_b$ are chosen similar to Ref. 28. Whereas the spectrum at $k_a = 0$ is almost indistinguishable from Fig. 4, we see a big difference at $k_a = \pi$. There is still hardly any spectral weight below the Fermi energy, but the band with largest spectral weight above the Fermi level is now located at approximately $\omega - \mu \approx 2.0$ and can be regarded as dispersionless.

From a qualitative point of view this can be explained by the dispersion of non-interacting fermions on a two-leg ladder in the presence of diagonal hopping, which is given by

$$\varepsilon(k) = -t_a \cos k_a - 2t_b \cos k_b - 2t_d \cos k_a \cos k_b,$$ \hspace{1cm} (14)$$

where the values for $k_a$ are restricted to 0 and $\pi$, and in these two cases the dispersion can be written explicitly.
as
\[ \varepsilon(k_a = 0, k_b) = -t_a - 2(t_b + t_d) \cos k_b \]  
and fluctuations along the ladders, which seem to be im-
\[ \varepsilon(k_a = \pi, k_b) = +t_b - 2(t_b - t_d) \cos k_b. \]  
This means that for \( k_a = 0 \) the bandwidth is determined
by the sum of \( t_b \) and \( t_d \), whereas for \( k_a = \pi \) it is set by
the difference of these two hopping processes. Since we used
\( t_b = t_d = 0.25 \), this fits perfectly to the spectrum shown
in Fig. 7. The sum is equal to the value of \( t_b \) used for
the calculations without diagonal hopping in Sec. III B
and the difference is equal to zero, which explains the
dispersionless band at \( k_a = \pi \).
The picture that evolves from our calculations is some-
what different to that obtained in first-principle and C-
DMFT calculations. To begin with, the bands obtained
from the LDA all disperse with periodicity \( 2\pi \) and not \( \pi \),
as observed experimentally, along the \( b \) direction. Moreover
we could not find any signature of a flattening of the
upper \( d_{xy} \) bands in the direction \( \mathbf{k} = (0, 0) \rightarrow (0, \pi) \)
when a diagonal hopping is included, which was reported
in Ref. 33. The main difference of our calculations to C-
DMFT results is that C-DMFT finds a metal-insulator
transition at some finite value of \( V \), and this transition
point is shifted downward significantly when \( t_d \) is
considered.\[ \] In contrast we find an insulating state at reason-
able values of \( U \) already for \( V = 0 \), even without the
inclusion of \( t_d \). The discrepancy to C-DMFT calculations
are very likely due to the fact, that the cluster used in
the C-DMFT calculations consisted only of a single rung,
and fluctuations along the ladders, which seem to be im-
portant in this system, have been neglected altogether.

D. Ordered phase

We investigate two different driving forces for the oc-
currence of a charge-order pattern, (i) the coupling of the
electrons to lattice degrees of freedom, and (ii) nearest-
neighbor Coulomb interaction, similar to Ref. 17.

Let us start our investigations with possibility (i), the
coupling to the lattice. In order to keep the calculations
simple, we consider static lattice distortions, as dis-
cussed in Sec. III I. The inclusion of dynamical phonon ef-
effects would pose a severe problem to the diagonalization
procedures, because for phonons the Hilbert space is a
priori of infinite size, and some truncation scheme has to
be applied.\[ \] Well converged results for the spectral
function in the presence of dynamical phonons have so far
only been achievable for the polaron and the bipolaron
problem.\[ \]

We assumed a zig-zag charge order pattern, justified
by experimental evidence:\[ \]
\[ z_i = z e^{i Q r_i}. \]  
In order to keep the calculations simple and the num-
ber of independent variables small, we did not consider an
additional variational parameter like a staggered chem-
ic potential. The proper value of the distortion \( z \) is
determined as discussed in Sec. III I.

Motivated by previous work\[ \] we set \( V_a = V_b = 1.3 \),
for this choice we expect the distortions to be close to
the experimental value of \( z_{\text{exp}} \approx 0.95 \) (in units of
0.05 Å). Indeed we found \( z = 0.911 \), which is close to
\( z_{\text{exp}}, \) and the mean-field parameter was \( \delta = 0.338.\) The
spectrum calculated with these values is shown in the top
plots of Fig. 5.

The spectral function shows similar features as in the
undistorted phase. For \( k_a = 0 \) the bands disperse with
periodicity \( \pi \), whereas for \( k_a = \pi \) no evidence for a dou-
bling of the unit cell can be found, and the periodicity is
\( 2\pi \). Nevertheless, the gap at \( \mathbf{k} = (0, \pi/2) \) is considerably
larger than for \( V = 1.3 \) without distortions, see Fig. 4.

An interesting quantity when considering charge-
ordering phenomena is the charge order parameter, which
we calculate as

\[ m_{\text{CDW}} = \frac{1}{N_c \langle n \rangle} \sum_j (\langle n_j \rangle - \langle n \rangle) e^{i Q r_j}, \]  
where the expectation value \( \langle n_j \rangle \) is calculated from the
V-CPT Green’s function, and \( \langle n \rangle = 0.5 \). The factor \( \langle n \rangle \)
in the denominator assures that the order parameter is
normalized to the interval \([0, 1]\). For \( V_a = V_b = 1.3 \)
and static distortions we obtained \( m_{\text{CDW}} = 0.65 \), which
means that the disproportion of charges is rather large.

Let us now consider possibility (ii), where the coupling
to the lattice is switched off, \( C = 0, \kappa = 0 \), and the charge
ordering is driven by the nearest-neighbor Coulomb in-
teraction. In order to make a connection to the results ob-
tained with lattice distortions, we calculate the spectral
function at a similar value of the charge order parameter.
We found that for \( V_a = V_b = 2.05 \) the order parameter is
\( m_{\text{CDW}} = 0.66 \), close to the value found above.

The spectral function is shown in the lower plots of
Fig. 5. The spectral features again look very similar to
the CDW=1\( V \)-CPT Green’s function, and \( \langle n \rangle = 0.5 \). The factor \( \langle n \rangle \)
in the denominator assures that the order parameter is
normalized to the interval \([0, 1]\). For \( V_a = V_b = 1.3 \)
and static distortions we obtained \( m_{\text{CDW}} = 0.65 \), which
means that the disproportion of charges is rather large.

The excitation energy near the \( \Gamma \) point, relevant for
IR experiments, can be read off from Fig. 5 to be roughly
4\( t_a \) with lattice distortions and 5\( t_a \) without distortions.
Although these excitation energies are not constant com-
pared to the disordered phase, calculations including the
lattice degrees of freedom give a better agreement to ex-
perimental IR absorption data,\[ \] which show neither a
shift of the 1 eV peak nor the appearance of new peaks
related to electronic transitions.
IV. RESULTS FOR COUPLED LADDERS

So far we studied only single ladders and neglected the inter-ladder couplings, since they are frustrated and one might assume that they are only of minor importance. Nevertheless our approach allows us to include these inter-ladder couplings by choosing an appropriate cluster geometry, as indicated on the right hand side of Fig. 1. Note that it is necessary to use a $2 \times 12$ super-cluster which allows for a commensurate charge order pattern across the cluster boundaries. For details of the treatment of super-clusters we refer the reader to Ref. 34.

The parameter values for the inter-cluster coupling are chosen in the following way. First-principle calculations have shown that the effective hopping between different ladders is very small, so we set $t_{xy} = 0.1 t_a$, and longer ranging hopping processes are neglected since the linear dimensions of the cluster are rather small. The values for the other parameters are the same as used for the calculations in Sec. III B.

In Fig. 3 the spectral function for $V_a = V_b = V_{xy} = 1.3$ is shown. For $k$ parallel to the $b$ axis one can easily see that the spectrum looks very similar to the spectrum of a single ladder (upper panel of Fig. 4). The main difference between single and coupled ladders is that the chemical potential is much larger in the latter case ($\mu \approx 3.0$), which is due to the frustrated inter-ladder bonds.

When turning to $k$ parallel to the $a$ axis the spectral function looks very different. The most striking feature is that there is hardly any dispersion of the bands, and the filled low-energy band can actually be considered as dispersionless. The spectral weight of this excitation, however, decreases significantly away from $k = 0$ and is transferred to unoccupied states above the Fermi level at approximately $\omega - \mu \approx 1.5$.

Let us now compare our numerical results to experimental data. Kobayashi et al. performed angle-resolved photo-emission spectroscopy (ARPES) at room temperature, where the system is in the disordered phase. For momentum transfer parallel to the $a$ direction they found no dispersion of the $V 3d$ bands, which fits perfectly well to our results. For $k$ along the $b$ axis a band dispersion of a 1D antiferromagnetic quantum system was found with experimental band with of approximately 0.06–0.12 eV. This value is rather small compared to the band width in our calculation of approximately 0.35 eV, see Fig. 3. We checked that the band width scales with the hopping along the ladder $t_b$ (not shown), and therefore this discrepancy between calculations and experiment can be shortened by choosing a smaller value for $t_b$, which does not significantly affect the charge ordering of the system. Nevertheless the strong difference between spectra along $a$ and $b$ direction are well described by our calculations.
V. CONCLUSIONS

In this paper we have applied the recently proposed generalization of the V-CPT for extended Hubbard models to the case of quarter-filled ladder compounds. We were thus able to perform the first theoretical study of the spectral function of $\alpha'$-NaV$_2$O$_5$ within the extended Hubbard model.

For single ladders in the disordered phase we found that in the channel $k_a = 0$ the system behaves like a one-dimensional antiferromagnetic insulator, and the gap is mainly determined by the nearest-neighbor Coulomb interaction on a rung. Our calculations suggest that the system is in an insulating phase for all values of $V$.

This picture still holds when a diagonal hopping $t_d$ is included in the Hamiltonian, which was suggested to be important by LDA and C-DMFT studies. We could show that for $k_a = 0$ hardly any changes can be seen in the spectral function, whereas for $k_a = \pi$ the bands become flat. These findings do not agree with LDA considerations\textsuperscript{39} where a flat upper band was observed for $k_a = 0$, thus requiring a finite value of $t_d$ in a tight-binding fit.

For the transition into the charge-ordered low-temperature phase we considered two driving mechanisms, the coupling to a static lattice distortion and the nearest neighbor Coulomb interaction. With lattice coupling we found, similar to Ref.\textsuperscript{17} that for $V = 1.3$ the distortion is close to the experimentally found size, accompanied by a large disproportion of charges. In order to reach the charge-ordered phase solely by Coulomb interactions, we had to use a large value of $V$ (with $V = 2.05$ for the same value of the order parameter), which resulted in a large gap in the spectral function, considerably larger than in the disordered phase and in the ordered phase with lattice distortions. Since IR experiments\textsuperscript{38} do not show such a discrepancy, we suggest that for the description of the ordered phase, lattice distortions cannot be neglected.

Within our approach it was straightforward to study the effects of inter-ladder coupling on the spectral function. We found that the spectra along the ladder direction are not significantly affected by these couplings. Perpendicular to the ladders the calculated bands are almost dispersionless, in good agreement with experimental data.
