ABSTRACT
For early-type galaxies, the correlations between stellar mass and size, velocity dispersion, surface brightness, colour, axial ratio and colour gradient all indicate that two mass scales, $M_* = 3 \times 10^{10}$ and $2 \times 10^{11} M_\odot$, are special. The smaller scale could mark the transition between wet and dry mergers, or it could be related to the interplay between supernovae (SNe) and active galactic nuclei (AGNs) feedback, although quantitative measures of this transition may be affected by morphological contamination. At the more massive scale, mean axial ratios and colour gradients are maximal, and above it, the colours are redder, the sizes larger and the velocity dispersions smaller than expected based on the scaling at lower $M_*$. In contrast, the colour–$\sigma$ relation, and indeed, most scaling relations with $\sigma$, are not curved: they are well described by a single power law, or in some cases, are almost completely flat. When major dry mergers change masses, sizes, axial ratios and colour gradients, they are expected to change the colours or velocity dispersions much less. Therefore, the fact that scaling relations at $\sigma > 150$ km s$^{-1}$ show no features, whereas the size–$M_*$, $b/a$–$M_*$ and colour–$M_*$ colour gradient–$M_*$ relations do, suggests that $M_* = 2 \times 10^{11} M_\odot$ is the scale above which major mergers dominate the assembly histories of early-type galaxies.

Key words: galaxies: elliptical and lenticular, cD – galaxies: evolution – galaxies: fundamental parameters.

1 INTRODUCTION
Recent work (Bernardi et al. 2010b) has shown that the colour–magnitude relation of early-type galaxies in the Sloan Digital Sky Survey (SDSS) differs significantly from a pure power law, curving downwards at low luminosity and upwards at high luminosity ($M_r > -20.5$ and $M_r < -22.5$, respectively). This is also true of the colour–size relation, and is even more apparent with stellar mass, where the corresponding mass scales are $M_* = 3 \times 10^{10} M_\odot$ and $M_* > 2 \times 10^{11} M_\odot$, respectively. The upward curvature at the massive end does not appear to be due to stellar population effects. Curvature in the colour–luminosity (or colour–$M_*$) relation at the faint end was noted before (e.g. Graham 2008; Skelton, Bell & Somerville 2009); the curvature at bright end is the new finding of Bernardi et al. (2010b).

Curvature at the low-mass end using other parameters (e.g. surface brightness) has been noted before as well (e.g. Kauffmann et al. 2003; Shankar et al. 2006); the subject of this Letter is to analyse non-linear scaling relations at the high-mass end, extending the analysis of Hyde & Bernardi (2009). We show that the curvature in the colour–$M_*$ relation coincides with curvature in other relations with $M_*$. However, when $M_*$ is replaced with velocity dispersion, then there is little curvature. Although curvature in scaling relations does not imply a change in the physics which sets the relations (e.g. Graham & Guzmán 2003; Graham 2010), we argue that our findings suggest that major dry mergers dominate the mass growth at $M_* > 2 \times 10^{11} M_\odot$.

Our results are based on two different ways of selecting early-type samples from the SDSS data base. One follows Hyde & Bernardi (2009): the image must be round ($b/a > 0.6$) and the light profile shape must be well-fitted by a deVaucouleurs profile (fracDev = 1). The other is a simple cut on how centrally concentrated the surface brightness is ($C_r > 2.86$). The former method produces a sample that is more purely elliptical; the latter contains many edge-on discs. See Bernardi et al. (2010a) for a more detailed discussion of these selection criteria, and of the SDSS photometric and spectroscopic...
parameters which we use below. Where necessary, we have assumed a spatially flat background cosmology with energy density dominated by a cosmological constant $\Lambda = 0.7$, with a Hubble constant $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$ at the present time.

2 CURVATURE IN RELATIONS WITH $M_*$, BUT NOT WITH $\sigma$

Fig. 1 shows correlations between stellar mass and (from top to bottom, left-hand panels) size, velocity dispersion and surface brightness and colour, axial ratio and colour gradient (top to bottom, right-hand panels) in the Hyde–Bernardi sample. (We discuss how we define the gradient in Section 3.2.) None of these correlations is pure power laws. Although the curvature at $\log_{10} M_*/M_\odot < 10.5$ is interesting – galaxies at the faint, low-mass end ($M_* \geq -20.5$, $\log_{10}(M_*/M_\odot) \leq 10.5$) tend to curve towards bluer colours, larger sizes, fainter surface brightnesses, smaller axial ratios and colour gradients – in what follows, we will focus on what appears to be a transition mass scale at higher masses. At $\log_{10} M_*/M_\odot > 11.3$, the relations curve towards larger sizes, smaller than expected velocity dispersions, fainter surface brightnesses (left-hand panels), and smaller axial ratios and smaller colour gradients (right-hand panels). This is precisely the mass scale on which the colour–$M_*$ relation curves towards redder colours (top right-hand panel).

Fig. 2 shows that when $M_*$ is replaced with velocity dispersion, there is little curvature at $\log \sigma/\text{km s}^{-1} > 2.2$. In fact, the correlations with surface brightness, colour gradient and axial ratio are almost completely flat. (That surface brightness and $\sigma$ are uncorrelated was noted by Bernardi et al. 2003.) The fact that there is no feature at the largest $\sigma$ in any of these relations, despite clear features in the scalings with $M_*$, is what has motivated this Letter.

In this context, it is important to note that the relation between $M_{\text{dyn}} \propto R_\sigma^2$ and luminosity or $M_*$ is very well described by a single power law over the entire range: the curvature in the sizes and velocity dispersions cancel (Fig. 3). Presumably, this is because the objects we observe are virialized, whatever their merger histories.

3 DISCUSSION

Major dissipationless mergers are expected to change the sizes in proportion to the masses, but to leave the velocity dispersions and colours unchanged. In contrast, minor dissipationless mergers produce larger fractional changes in size than in mass, and decrease the velocity dispersions and colours (see appendix C in Bernardi et al. 2010b for details). Therefore, the curvature in the correlations between $M_*$ and size, $\sigma$ and color, which have been noticed before,
3.1 Axial ratios

The $b/a-M_*$ relation (right centre panel of Fig. 1) deserves further comment. Van der Wel et al. (2009) report that the width of the $b/a$ distribution changes at $\log(M_*/M_\odot) \sim 10.5$. They interpret this as evidence that, above this mass, assembly histories are dominated by major mergers. Our results suggest this is not the full story.

In Fig. 1 we have shown two versions of this relation, because the Hyde–Bernardi selection requires $b/a > 0.6$. In this sample, $b/a$ decreases at $\log(M_*/M_\odot) > 11.3$. However, note that this decrease is even more marked in the sample selected to have $C_i > 2.86$, where no cut on $b/a$ is applied. Compared to the Hyde–Bernardi sample, this sample has considerably smaller $b/a$ at small $M_*$: Bernardi et al. (2010a) show that this is primarily due to an increased incidence of discs and contamination by Sa galaxies, because the $C_i > 2.86$ sample is not as purely elliptical/early-type as the Hyde–Bernardi sample. We believe this change in morphological mix is the primary reason why Van der Wel et al. saw what they did.

We believe the real feature of interest is the drop in $b/a$ at $\log(M_*/M_\odot) > 11.3$ where (Bernardi et al. 2010a show that) morphological mix is no longer an issue. Van der Wel et al. also see this drop, but they dismiss it. Instead, we believe the narrowing of the distribution at $\log(M_*/M_\odot) \sim 10.5$ marks the transition from dissipational to dissipationless histories, or a change in relatives importance of supernovae (SNe) and active galactic nuclei (AGNs) feedback (e.g. Kauffmann et al. 2003; Shankar et al. 2006), while the decrease in $b/a$ at $\log(M_*/M_\odot) > 11.3$ marks the transition to major dry mergers. This decrease has been expected for some time (see González-García & van Albada 2005; Boylan-Kolchin, Ma & Quataert 2006; Ragone-Figueroa & Plionis 2007; Ragone-Figueroa et al. 2010) – it was first found by Bernardi et al. (2008). This is thought to indicate an increasing incidence of major radial mergers, since these would tend to result in more prolate objects.

3.2 Colour gradients

The right bottom panel of Fig. 1 shows that colour gradients – here defined to be the difference between the model and Petrosian samples have all been discussed in this context (e.g. Davies et al. 1983; Matković & Guzman 2005; Bernardi et al. 2007; Hyde & Bernardi 2009; Bernardi et al. 2010a,b). What is new here is the recognition that these all occur at the same mass scale, that this mass scale is also important for axis-ratios and color-gradients, and, significantly, that the curvature is absent when $M_*$ is replaced by $\sigma$.

Figure 2. Curvature in the correlations between velocity dispersion and (from top to bottom, left-hand panels) size, stellar mass and surface brightness and colour, axial ratio and colour gradient (top to bottom, right-hand panels), in the Hyde–Bernardi sample. The dashed lines mark the scales where one would expect to see a change in the slope of the relations based on Fig. 1. Scalings in a sample selected to have $C_i > 2.86$ are shown only where they differ from the scalings in the Hyde–Bernardi sample.
for why none of the scaling relations in Fig. 2 shows any feature at log $\sigma$/km s$^{-1}$ > 2.2, and those that are most clearly sensitive to merger histories are almost completely flat.

Mergers are not the only way to produce or alter colour gradients. In some models, gradients are related to feedback and winds (Pipino et al. 2010). Our demonstration that gradients scale differently with $M_*$ than with $\sigma$ may have interesting implications for such models. In addition, producing the downturn, we see, at log($M_*/M_\odot$) > 11.3 is an interesting challenge for such models, as is relating this to the changes in size, $\sigma$ and $b/a$ we have found. Because the major dry merger model provides a simple framework for understanding all these relations, our results suggest that $M_* > 2 \times 10^{11}$ $M_\odot$ is the scale above which major dry mergers dominate the assembly history.

4 IMPLICATIONS

We have found that a variety of early-type galaxy scaling relations – the size–$M_*$, $b/a$–$M_*$, colour–$M_*$ and colour–gradient–$M_*$ relations – all show departures from a pure power law at $M_* = 2 \times 10^{11}$ $M_\odot$, whereas there is no such feature when $M_*$ is replaced with $\sigma$. Since major dry mergers are expected to change the sizes, axial ratios and colour gradients of galaxies while leaving the velocity dispersion and colour unchanged, our findings suggest that the total stellar mass in early types with $M_* > 2 \times 10^{11}$ $M_\odot$ today must have grown primarily by relatively recent major dry mergers. In Bernardi et al. (2010b), we argue that such mergers may be required to reconcile the $z \sim 1$ counts of objects with $M_* > 2 \times 10^{11}$ $M_\odot$ with those at $z \sim 0$.

This particular mass scale also appears in analyses of a local sample (higher quality data, but significantly smaller sample), where it is identified with the transition to dry mergers (see page 270 and related discussion in Kormendy et al. 2009). It is special in hierarchical models also. Fig. 3 of Guo & White (2008) shows that below $1.6 \times 10^{11}$ $M_\odot$ star-formation has been a significant part of the mean stellar mass growth rate (much of it through wet mergers), whereas the stellar mass growth at masses above this occurs only through dry mergers. See Hopkins et al. (2008) and Eliche-Moral et al. (2010a,b) for other arguments suggesting dry mergers since $z \sim 1$ are a natural and necessary part of the assembly history at $M_* > 2 \times 10^{11}$ $M_\odot$. While it is reassuring that many lines of study all identify this same mass scale, we feel it worth emphasizing that our analysis suggests that above this mass scale, the mergers were not just dry – they were major. In this respect, there is some tension between our conclusions, and recent work which argues that although the mass in the central kpc or so of early-type galaxies has not grown since $z \sim 2$, the half-light radii have increased by more than a factor of two. This suggests that, since $z > 2$, mass has been added to the outer regions only: this sort of inside-out scenario for the growth is most easily understood if the mergers were minor (e.g. Lapi & Cavaliere 2009; Cook et al. 2009; Bezanson et al. 2009). However, as Tiret et al. (2010) note, the observation of constant mass in the central regions does not, by itself, exclude major mergers. In the simulations of Gao et al. (2004), as an object assembles its mass through major dry mergers, the mix of particles in the central regions can change dramatically, even though the total mass in the central regions remains constant. Our finding that color-gradients are erased at large masses may be indicating that this is indeed what happens at $M_* > 2 \times 10^{11}$ $M_\odot$.

Finally, it is interesting to ask how BCGs, which are amongst the most massive objects in the local Universe, fit into this picture? Compared to non-BCGs of similar mass or luminosity, their colors
are slightly redder (Roche et al. 2010; fig. 10 in Bernardi et al. 2010b), they have smaller color gradients (Roche et al. 2010), and slightly larger sizes (Bernardi 2009). Whereas the first two are in agreement with our major merger picture, the last suggests more size growth than is usually associated with major mergers. Hence, it may be better to think of BCG formation as a two step process. In the first, the major mergers which result in the object becoming a BCG erase its color gradient (and decrease $b/a$; Bernardi et al. 2008); thereafter, minor mergers puffed up its size. Tidal stripping during the minor merger may also have contributed to the formation of intracluster light in its host halo (Bernardi 2009; Bernardi et al. 2010b). This two step picture is in striking agreement with a detailed analysis of the age, metallicity and abundance gradients of BCG NGC 4889 (Coccato et al. 2010).
