Abstract. Background/Aim: Patella baja (PB) and pseudo-patella baja (PPB) have been shown to negatively influence outcomes after total knee arthroplasty. We hypothesized that there is a high incidence of PB and PPB after megaprosthetic total knee arthroplasty (M-TKA), and that this is associated with reduced range of motion. Patients and Methods: We retrospectively analysed all patients in our Orthopaedic Trauma Department after distal femur or proximal tibia replacement. Preoperative and one-year postoperative follow-up included measurement of range of motion and detection of PB and PPB using radiological indices. Results: We included 44 patients (age: 73±19 years). Preoperative PB detected by ISI could be reduced from 13 (36%) to 11 (25%) (p<0.01). Preoperative vs. postoperative ISI was 0.88±0.23 vs. 1.06±0.45 (p=0.03). PPB was observed preoperatively in 23 (63%) patients vs. 24 (54%) postoperatively. Preoperative vs. postoperative CDI was 0.70±0.24 vs. 0.95±0.43 (p=0.002). Preoperative flexion was 91°±30° vs. 85°±24° postoperatively (p>0.05). Conclusion: Both PB and PPB are frequently observed after M-TKA. A reduction in PB and PPB alone does not improve postoperative range of motion.

Physiological patellofemoral joint movement is important for normal knee function, i.e., flexion, extension, and force transmission. Patella baja (PB) is a real shortening of the patellar tendon, and pseudo-patella baja (PPB) is a relative shortening of the patellar tendon by elevation of the tibial plateau. PB and PPB are known to affect patellofemoral joint movement; a shortening of more than 10% of the patellar tendon is assumed to significantly reduce knee flexion due to the reduced length of the extensor apparatus (1-3). The consequences of PB and PPB are muscular imbalance and mechanical retropatellar overload, both of which can cause patellofemoral pain syndrome (3, 4). In PB, the patellar tendon is at risk for rupture due to higher contact forces and an impingement-like situation of the patella against the tibial component (5). A relevant joint line elevation of more than 5-8 mm is believed to be clinically relevant and cause mid-flexion instability (6, 7).

Landmarks for joint line restoration in total knee arthroplasty (TKA) include the femoral epicondyles, the adductor tubercle, the fibular head, the tibial tubercle, and the inferior patellar pole (7). PB and PPB can be defined by measuring the Insall-Salvati index (ISI), the modified Insall-Salvati index (mISI), the Caton-Dechamps index (CDI), and the Blackburne-Peel index (BPI) on lateral knee x-rays in 45° knee flexion (3, 8, 9). The postoperative incidence of PB ranges from 0.7% to 37%, depending on the operative method (2, 5, 10, 11). PPB can be found in 25% to 47% of patients after primary TKA (2, 12). Behrend et al. have shown that PPB predicts impaired postoperative outcome with reduced range of motion after primary TKA. Chiang et al. have observed 58% and 82% incidence of PB and PPB, respectively, after revision TKA.

The incidence of PB and PPB and their relationship to clinical function after implantation of a distal femur or proximal tibia replacement remains unclear. The aim of this study was to evaluate incidence of PB and PPD and their relationship to function after megaprosthetic total knee arthroplasty (M-TKA).

Patients and Methods

We retrospectively analyzed all patients in our orthopaedic trauma department who underwent a MUTARS® distal femur or proximal tibia replacement (Implantcast GmbH, Buxtehude, Germany) between 1998 and 2017. At the one-year follow-up (1y-fup) all patients who had lateral knee x-rays and documented range of motion (ROM) were available for analysis.
ROM was measured by a trained orthopaedic surgeon with a goniometer. Preoperative and postoperative lateral knee x-rays were analyzed by a trained, independent orthopaedic surgeon with the PACS (Centricity Enterprise Web version 3.0, GE Medical Systems, Milwaukee, WI, USA). An exact lateral radiograph was defined by the projection of both posterior femoral condyles over each other. Radiological measurements included for detection of PB were the Insall-Salvati Index (ISI) and the modified Insall-Salvati Index.
(mISI). For detection of PPB, we measured the Blackburne-Peel Index (BPI) and the Caton-Dechamps Index (CDI) (Figure 1). The presence of PB was defined as mISI <1.2 (9, 10, 12, 13) and the presence of PPB as BPI <0.54 (14).

At least verbal informed consent was obtained from all individual participants who were included in the study. The study was approved by the local ethics committee (Nr 7957_BO_S_2018).

Statistical analysis. As the trial was of exploratory nature, no sample size calculation was performed. Data were summarized using Microsoft Excel® software and statistical analysis was performed with IBM SPSS Statistics® Version 25. Data were tested for normal distribution with the Kolmogorov Smirnoff Test. The t-test was used for comparative statistics for parametric data. The Mann-Whitney U-test was used for comparative statistics for non-parametric data. Correlation testing was performed using Pearson correlation for parametric variables and Spearman correlation for non-parametric variables. Data is presented as mean±standard deviation. Significance was defined at \( p=0.05 \).

Results

Demographic data. We included 44 patients with a mean age of 73±19 years. Out of these, 28 (63%) were female and 16 (37%) were male. Mean body mass index (BMI) was 26±4. Indication for M-TKA was periprosthetic fracture (n=14), tumour (n=12), infection (n=8), traumatic fracture (n=6), aseptic loosening (n=2), and pathologic fracture (n=2). M-TKA was performed as the primary surgery in 20 patients and as revision surgery in 24 patients.

Radiological measurements. Preoperatively lateral knee x-rays were available in 36 patients and postoperatively in 44 patients. In 8 patients, preoperative lateral x-rays were missing or not assessable due to trauma. PB could be observed by ISI in 13 (36%) patients preoperatively vs. 11 (25%) patients postoperatively \((p<0.01)\), by mISI in 10 (28%) patients preoperatively vs. 12 (27%) patients postoperatively, and by CDI in 10 (28%) patients preoperatively vs. 11 (25%) postoperatively. The mean preoperative and postoperative ISI was 0.88±0.23 vs. 1.06±0.45 \((p=0.03)\), and the mean mISI was 1.30±0.37 vs. 1.49±0.51 \((p=0.06)\). PPB was observed in 23 (63%) patients preoperatively vs. 24 (54%) postoperatively. The mean CDI was 0.70±0.24 preoperatively vs. 0.95±0.43 postoperatively \((p=0.002)\) and the mean BPI was 0.47±0.22 preoperatively vs. 0.57±0.39 postoperatively \((p=0.177)\) (Table I, Figure 2).

In cases of distal femur replacement only, significant differences in CDI preoperatively and postoperatively were found (0.64±0.12 vs. 0.85±0.23; \(p<0.01\)). In cases of proximal tibia replacement only, ISI \((1.09±0.20 vs. 1.63±0.13; p<0.01)\) and mISI \((1.68±0.14 vs. 2.17±0.14; \ p<0.01)\) showed significant higher values postoperatively. In cases of combined distal femur replacement and proximal tibia replacement, no differences between preoperative and postoperative values in ISI, mISI, CDI and BPI were observed \((p>0.05)\). Postoperatively, distal femur replacement showed significant higher ISI, mISI, CDI and BPI than proximal tibia replacement (each: \(p<0.01\), but not in cases with combined distal femur and proximal tibia replacements (Figure 3).

| Table I. PB and PPB indices as measured on lateral knee x-rays. |

PB: Patella baja; PPB: pseudo-patella baja; ISI: Insall-Salvati index; mISI: modified Insall-Salvati index; CDI: Caton-Dechamps index; BPI: Blackburne-Peel index.

Figure 2. Preoperative and postoperative PB and PPB indices. Grey: preoperative indices; white: postoperative indices.
Revision surgery. Whereas a reduced CDI could be observed preoperatively in cases of revision surgery compared to primary surgery (0.64±0.22 vs. 0.81±0.26; p=0.037), no differences between primary surgery and revision surgery could be observed postoperatively for ISI, mISI, CDI, and BPI (p>0.05) (Figure 4). No differences between preoperative and postoperative ISI, mISI, CDI and BPI were observed in cases of primary surgery (p>0.05). CDI showed higher values postoperatively than preoperatively in cases of revision surgery (0.64±0.21 vs. 0.90±0.39; p<0.01). ISI, mISI, and BPI tended to be higher postoperatively (p<0.1). We could not show any influence of age or BMI on the incidence of PB or PPB.

Range of motion. Preoperative range of motion was obtained in non-traumatic patients, except 22 who were not able to participate due to pain. Knee flexion was 91°±30° preoperatively vs. 85°±24° postoperatively (p=0.05). Extension gap was 5°±9° preoperatively vs. 4°±8° postoperatively (p=0.05). Postoperatively, we did not observe any significant reduction in the extension gap (5° vs. 4°; p=0.32) or knee flexion (80° vs. 86°; p=0.25) in patients with PB compared to those without PB. Patients with PPB showed a tendency for a larger extension gap compared to those without PPB (5° vs. 2°; p=0.16). Flexion tended to be reduced in patients with PPB compared to those without PPB (81° vs. 89°; p=0.12). Poor correlations between ISI, mISI, CDI, and BPI and range of motion were observed.

Discussion

In this study, we have described the incidence of PB and PPB in patients with megaprosthetic knee arthroplasty, including distal femur and proximal tibia replacements. We showed that at 1y-fup, PB could be reduced postoperatively from 36% to 25% and PPB from 63% to 54%. These results are comparable to those in the literature after primary TKA for PB (0.7-37%) and for PPB (25-47%) (2, 12). However, while PB and PPB have been associated with a poorer outcome in primary TKA, we did not observe differences in range of motion after M-TKA (2, 5, 10, 11). This was in accordance with Chiang et al., who also did not find any association between PB and PPB and decreased range of motion, which might be explained by preexisting reduced ROM preoperatively (3).

During revision surgery, preoperative PB and real shortening of the patellar tendon can be substantially reduced by intraoperative arthrolysis; consequently, we did not observe differences in postoperative patellar tendon length compared with patients undergoing primary surgery. Furthermore, no difference in ROM could be observed between patients with PB and patients without PB, suggesting that a minor shortening of the patellar tendon can be tolerated (1, 6, 15-17). Shortening of the patellar tendon by more than 10% is expected to significantly reduce the knee flexion. With this assumption, we expected an improved range of motion in patients undergoing revision surgery with a postoperatively lengthened patellar tendon and reduced PB (1-3, 18). However, we did not observe improved flexion or reduced extension gap postoperatively. When comparing postoperative PPB to preoperative measurements, we observed an improvement in CDI but did not observe an improvement in patella height measured by BPI. Patients with postoperative PPB tended to show...
reduced flexion compared to patients without PPB. Therefore, we believe that PPB and exact joint line reconstruction are at least of equal importance for improvement of postoperative ROM.

The clinical relevance of joint line elevation is controversial. Generally, it is believed that a relevant joint line elevation of more than 4 mm is associated with retropatellar pain due to increased contact forces (relative overstuffing) and altered quadriceps mechanics (2, 10, 19). By contrast, minor joint line elevations do not seem to influence the postoperative clinical outcome after primary TKA (2, 4, 6, 13, 17, 20).

Whereas stability in extension and flexion by different extension and flexion gap sizes is a critical point in joint line reconstruction in primary TKA, in megaprosthetic TKA, this difficulty is avoided by a constrained endoprosthesis design. More importantly, in M-TKA, joint line referencing and reconstruction can be achieved by preoperative planning with length measuring of the resected bone to determine the size of the modular endoprosthesis. Additive reconstruction of bone loss can be achieved by bone grafting or metal augmentations (15, 21). Larger defects require a modular revision endoprosthesis such as the MUTARS system used here. Landmarks for joint line referencing are the femoral epicondyles, the adductor tubercle, the fibular head, the tibial tubercle, and the inferior patella pole (7, 22, 23). If none of the mentioned landmarks are available, such as in severe traumatic injuries like floating knee injuries, referencing of the contralateral side could help to restore the joint line. Exact joint line reconstruction seems to be an important factor in postoperative ROM.

Limitations

Major limitations of this study are firstly the small and heterogeneous study cohort and the retrospective follow-up. Secondly, although we could observe a PPB in 54% of our patients with a trend towards decreased flexion, no significant differences could be observed. We performed a post hoc power analysis and due to the small sample size, we could only acquire a power of 26%. While we are limited by low power, we think a trend towards reduced flexion can be seen. Thirdly, range of motion alone is not a holistic tool for determination of functional outcome. Future studies should be performed with further clinical scores to gain a clearer understanding of postoperative function.

Lastly, the radiographic analysis has some inherent limitations as the exact position of the patient is an important presumption. For final determination of PB, we used the mISI as it has been shown to be less related to patient positioning and patella shape compared to ISI and CDI (20, 24).

Conclusion

Both PB and PPB are frequently observed after M-TKA with an incidence of 25% and 54%, respectively. However, a reduction of PB and PPB alone does not improve postoperative range of motion.
