Improved Li storage performance in SnO$_2$ nanocrystals by a synergetic doping

Ning Wan$^1$, Xia Lu$^2$, Yuesheng Wang$^3$, Weifeng Zhang$^1$, Ying Bai$^{1,4}$, Yong-Sheng Hu$^3$ & Sheng Dai$^4$

Tin dioxide (SnO$_2$) is a widely investigated lithium (Li) storage material because of its easy preparation, two-step storage mechanism and high specific capacity for lithium-ion batteries (LIBs). In this contribution, a phase-pure cobalt-doped SnO$_2$ (Co/SnO$_2$) and a cobalt and nitrogen co-doped SnO$_2$ (Co-N/SnO$_2$) nanocrystals are prepared to explore their Li storage behaviors. It is found that the morphology, specific surface area, and electrochemical properties could be largely modulated in the doped and co-doped SnO$_2$ nanocrystals. Gavalnostatic cycling results indicate that the Co-N/SnO$_2$ electrode delivers a specific capacity as high as 716 mAh g$^{-1}$ after 50 cycles, and the same outstanding rate performance can be observed in subsequent cycles due to the ionic/electronic conductivity enhancement by co-doping effect. Further, microstructure observation indicates the existence of intermediate phase of Li$_3$N with high ionic conductivity upon cycling, which probably accounts for the improvements of Co-N/SnO$_2$ electrodes. The method of synergetic doping into SnO$_2$ with Co and N, with which the electrochemical performances is enhanced remarkably, undoubtedly, will have an important influence on the material itself and community of LIBs as well.

High-energy lithium-ion batteries (LIBs) have already played a crucial role in the development of consumer electronics, electric vehicles, and grid-scale stationary energy storage. As expected, there has been a growing demand for LIBs with improved electrochemical performance with regard to higher energy density, longer cycle life and extreme safety$^{1-7}$. When it refers to practical battery applications, the energy density (per weight or volume), cycle life, and safety issues, the major focuses of recent battery research, are also the most important factors considered for next-generation high-performance LIBs. Currently, graphite is a commonly used anode material in commercial LIBs. However, it is far from ideal one due to its low initial coulombic efficiency, large amount of solid electrolyte interphase (SEI) formation, and asymmetric discharge/charge process$^{8,9}$. Compared with other anode candidates, graphite also lacks a capacity advantage (vs. crystal/amorphous silicon), the rate capability (vs. Li$_4$Ti$_5$O$_12$ spinel), and some other favorable characteristics. Therefore great effort is being devoted to balancing the major requirements of the qualified anode for LIBs$^9$.

According to various reports, metal-oxide anodes demonstrate attractive prospects after effective modifications. Tin dioxide (SnO$_2$), particularly, has been widely investigated for its lithium (Li) storage mechanism of an initial phase conversion reaction followed by a Li-Sn alloying reaction to deliver a theoretical specific capacity of 1494 mAh g$^{-1}$ ($\text{SnO}_2 + 4 \text{Li}^+ + 4 e^- \rightarrow 2\text{Li}_2\text{O} + \text{Sn}; \text{Sn} + 4.4 \text{Li}^+ + 4.4 e^- \leftrightarrow \text{Li}_4.4\text{Sn}$)$^{10-13}$. Although the specific capacity is around four times larger than that of a graphite anode, SnO$_2$ electrode suffers from poor cycleability, with obvious capacity loss after repeated cycling. This capacity loss is mainly caused by the severe particle pulverizations that is triggered by a more than 250% volume change (expansion and shrinkage) upon lithiation/delithiation$^{13,14}$. Upon long cycles, the pulverization of SnO$_2$ particles is directly associated with a decay in capacity, as uncontrolled volume variations lead to cracking of the electrode, which in turn causes a loss of direct contact with current collector and the electronic conductivity network. This volume change also induces additional growth of SEI layers on the naked SnO$_2$ surface, thereby introducing a corresponding mechanical instability$^{13,16}$. Moreover, the poor cycleability inevitably results in serious capacity fading upon cycling, especially at high current densities$^{13}$. Thus it is essential to

improve the cycleability of SnO2 electrodes by suppressing particle pulverization and volume change, and further enhancing the electronic conductivity network to ensure superior electrochemical performances for use in LIBs.

Among the available techniques, element doping is an effective method that works well to optimize the electrochemical performance of SnO2 electrodes. Recently, cobalt (Co) has been successfully doped into the SnO2 lattice and it was found that the doped samples exhibit a volume buffering effect (i.e., being able to accommodate a large volume change) and enhanced electronic conductivity. In work by Chien-Te et al., a Co-doped SnO2 electrode released a specific capacity of only about 530 mAh g\(^{-1}\) after 50 cycles, much lower than its theoretical value (for alloying/de-alloying reaction ~782 mAh g\(^{-1}\) and for alloying/de-alloying and conversion reactions, ~1494 mAh g\(^{-1}\)). On the other hand, it is well established that nitrogen (N)-doped SnO2 exhibits desirable enhanced electrical and optical properties, which could be attributed to greatly increased electronic conductivity. Therefore, synergetic doping of Co and N into an SnO2 sample should take advantage of the enhanced volume tolerance as well as good electronic conductivity, which would endow the SnO2 electrode with better Li storage and transport behaviors.

This article details the application of a hydrothermal method to prepare nanocrystal SnO2 and Co-doped SnO2 (Co/SnO2) samples. After the Co-doped sample was synthesized, it was further thermally treated under N2 atmosphere to obtain Co and N co-doped SnO2 (Co-N/SnO2), which has rarely been reported in previous literatures. All of the samples are employed as anodes for cycling tests. It is found that the Co and N co-doped material exhibits remarkably improved electrochemical properties as a result of the synergetic contributions from the Co and N. Recently, as demonstrated by our group, Cu-N and Ni-N co-doped SnO2 also shown enhanced electrode performances. However, the improvement mechanism has not been intensively explored yet. In this work, not only the electrochemical performance influence of Co-N co-doping on SnO2 are extensively studied, more significantly, the intrinsic mechanism is also discussed and revealed. This work paves the way to fully understanding the Li storage and transport mechanism in this important material. Further, it also sheds light on novel structural design and composition-modulated synthesis of electrode materials in advanced LIBs.

**Results and Discussion**

**Morphology and structure analysis.** Figure 1 shows the XRD patterns of as-prepared phase-pure SnO2, Co/SnO2, and Co-N/SnO2 nanocrystals. The prominent peaks of three samples can be easily identified as the tetragonal phase of SnO2 (JCPDS card no.01-0657).

![XRD patterns of the as-prepared samples](image)

**Table 1.** Lattice parameters and grain sizes of pure SnO2, Co/SnO2 and Co-N/SnO2 samples.

| Samples     | a/Å  | c/Å  | grain size/nm |
|-------------|------|------|---------------|
| SnO2        | 4.7655 | 3.1843 | 34.0          |
| Co/SnO2     | 4.7754 | 3.1854 | 35.6          |
| Co-N/SnO2   | 4.7973 | 3.1993 | 39.2          |

Raman spectroscopy is a more sensitive probe of structural distortion and lattice symmetry in solids, especially for the short-range and long-range ordering of materials. Figure S1 (Supporting Information) displays the
Raman spectra of the pure SnO$_2$, Co/SnO$_2$ and Co-N/SnO$_2$ samples. Three vibration peaks located at 472, 630, and 774 cm$^{-1}$ correspond to the Eg, Ag, and B$_2$g modes of rutile SnO$_2$, respectively; and the other three vibrations at 357 (IF), 440 (N1) and 571 (P) cm$^{-1}$ relate to its surfactants$^{25}$. It is reported that the intensity of P peak decreased with the growth of SnO$_2$ grains$^{23}$. From Figure S1, the intensity ratio of A$_{1g}$/P in the Co-N/SnO$_2$ sample is higher than those of the pure SnO$_2$ and Co/SnO$_2$ samples, indicating the growth in grain size after Co and N co-doping into the SnO$_2$ sample, in line with the trend derived from XRD as shown in Table 1. Additionally, the fitting results give the widths (full-width at half-maximum, FWHM) of 24, 22, and 16 cm$^{-1}$ for the A$_{1g}$ mode of the pure SnO$_2$, Co/SnO$_2$, and Co-N/SnO$_2$ samples, respectively, which means that the Co and N co-doping sample displays better crystallinity compared with the pure SnO$_2$ sample.

FESEM images of SnO$_2$, Co/SnO$_2$, and Co-N/SnO$_2$ samples are demonstrated in Fig. 2. The three as-prepared samples are clearly composed of nano-sized SnO$_2$ particles of less than 100 nm. Pure SnO$_2$ demonstrates a peculiarly hierarchical structure with an average diameter of 500 nm, which is agglomerated by initial nano-cubes (with side length of about 80 nm). Note that the Co doping and Co/N co-doping process changes the morphology of SnO$_2$. As clearly observed in Fig. 2b,c, Co/SnO$_2$ and Co-N/SnO$_2$ samples are composed of homogeneously distributed nanoparticles with a similar size of about 30 - 40 nm, much smaller than that of the pure SnO$_2$ sample (~80 nm). This reduction in particle size will effectively shorten the diffusion path of Li$^+$ during electrochemical cycling and thus facilitates a fast charge/discharge process. In addition, the smaller particle size is believed to be beneficial in releasing the interior stresses of SnO$_2$ particles and alleviating the influence of volume change upon lithiation/delithiation. The EDAX spectra and element mapping images of the Co/SnO$_2$ and Co-N/SnO$_2$ samples are demonstrated in Figure S2 (Supporting Information), which not only proves the existence of Co (and N) in the corresponding materials, but also indicates a homogeneous distribution of the doped elements.

The textural properties of pure SnO$_2$, Co/SnO$_2$, and Co-N/SnO$_2$ samples were determined by N$_2$ adsorption spectroscopy. Figure 2d,e, and f depict the N$_2$ adsorption/desorption isotherms of the phase-pure matrix, as well as those of the composite materials and the corresponding pore size distributions determined by the Barrett-Joyner-Halenda (BJH) model (inset Fig. 2d–f). The isotherms are of type IV adsorption and exhibit H4 hysteresis characterized by a well-defined and steep N$_2$ uptake step in a wide relative pressure (P/P$_0$) range of 0.60 – 0.90, which is the result of capillary condensation in mesoporous materials. Moreover, the increase in the amount of nitrogen adsorbed at low pressures (P/P$_0 = 0 – 0.1$) indicates the presence of nanopores. The BET specific surface areas of the pure SnO$_2$, Co/SnO$_2$, and Co-N/SnO$_2$ samples are respectively 123, 130, and 139 m$^2$ g$^{-1}$, indicating an increasing tendency after Co and N doping. Additionally, the BJH pore diameters for the three samples are determined to be 8.7, 8.9, and 9.1 nm, respectively (in Supporting Information Table S1). It can be
seen that the as-prepared Co-N/SnO₂ nanostructure exhibits increases in both BET surface area and pore diameter with respect to pristine SnO₂ and Co/SnO₂ samples, which are indeed beneficial for electrolyte penetration and electrode kinetics during cycling.

HRTEM images of pristine, Co/SnO₂, and Co-N/SnO₂ nanoparticles are displayed in Fig. 3. From the HRTEM images, the SnO₂ nanocrystals exhibit the homogenous particle sizes and visible lattice stripes. In Fig. 3a, the sharp (110) lattice stripes correspond to d-spacings of 0.335, 0.337, and 0.338 nm of rutile SnO₂ lattice at the [001] zone axis, which is consistent with the d-spacing of a rutile SnO₂ (110) plane shown in Fig. 3d. No other planes or d-spacing values are distinctly detected to be assigned to the impurity phases. These findings are further confirmed by the selected area electron diffraction (SAED) (shown in the inset), which demonstrates the regular electron diffraction patterns of pure/doped SnO₂ samples at the [001] zone axis. From Fig. 3, it can be seen that there is almost no difference in the structure of rutile SnO₂ before/after Co and Co/N co-doping, and no obvious impurity phases can be observed either in the bulk or on the surface, which is in good agreement with XRD measurements, as shown in Fig. 1.

The doping samples are further verified through XPS analysis. Figure 4a shows the XPS survey spectra of the Co/SnO₂ and Co-N/SnO₂ samples, from which the XPS signals of Co and a small amount of N can be observed unambiguously for Co-N/SnO₂. The binding energies of Co 2p for Co/SnO₂ and Co-N/SnO₂ samples are compared as shown in Fig. 4b, where the Co 2pₓ/₂ (780.5 eV) and Co 2p₁/₂ (796.2 eV) XPS binding energies for the two samples are detected at almost the same positions, confirming the presence of the same chemical environment Co²⁺ ions in the as-prepared samples (here, Co²⁺ ions substituting for Sn⁴⁺ ion as CoSn₂O₄)²⁶,²⁷. This result also implies that doping N into the SnO₂ lattice does not influence the chemical states of Co²⁺ ions in Co/SnO₂ samples. On the other hand, Co²⁺ ions are well-known to be electrochemically inactive in the voltage range of 0 to 3 V²⁸. Therefore, the presence of inactive Co²⁺ ions should be helpful in stabilizing the structure and affording the volume change for a SnO₂ electrode upon cycling. The binding energies of N 1s are detected at 394.9 and 398.3 eV on sample Co-N/SnO₂ (Fig. 4c), which clearly demonstrates the successful incorporation of N species in SnO₂ crystal structure²⁹. This nitrogen doping behavior is presumably ascribed to the decomposition of nitrate at 500°C during sample annealing³⁰, in consistence with the N element mapping result as shown in Figure S2k. The existence of N in the Co-N/SnO₂ nanocrystals will be beneficial in facilitating electronic conductivity²⁰,²¹, which will be discussed in the following sections.

Electrochemical performances. Figure 5a shows the initial charge/discharge profiles of pure SnO₂, Co/SnO₂, and Co-N/SnO₂ electrodes between 0.005 and 3.0 V under a current density of 0.1 C (1 C = 782 mA g⁻¹).
In Fig. 5a it appears that, of the three electrodes, the Co-N/SnO₂ electrode demonstrates the highest initial charge and discharge capacities, which could be attributed to its improved crystallinity and good electronic conductivity. On the other hand, the irreversible capacities for pure SnO₂, Co/SnO₂, and Co-N/SnO₂ are respectively 523, 653, and 709 mAh g⁻¹ in the first cycle. One important reason for the large capacity loss of the Co-N/SnO₂ electrode lies in the increased specific surface area, as shown in Table S1, which will inevitably result in excess formation of SEI film on the electrode surface. Although the three samples show similar trends in initial discharge/charge profiles, the Co-N/SnO₂ electrode exhibits two plateau-like discharge profiles at around 0.94 and 0.23 V, which can be separately ascribed to the structural destruction of SnO₂ at ~1.0 V vs. Li and formation of an intermediate SnO phase (2Li⁺ + SnO₂ → Li₂SnO₂ (SnO + Li₂O)). Subsequently, intermediate-phase SnO is further reduced to metallic Sn (2Li⁺ + Li₂SnO₂ → 2Li₂O + Sn) and then the alloying reaction of Sn with Li occurred. These processes have clear reduction peaks in the cathodic segment of the CV for Co-N/SnO₂ electrode, namely, the sharp peaks at about 0.90 and 0.21 V. In the initial charging process, the oxidation of Sn to Sn⁴⁺ (SnO) and further to Sn⁶⁺ (SnO₂) could be inferred in combination with CV characterization, which will be discussed later. From Fig. 5a it can be clearly seen that the plateau capacities at ~0.90 V are around 290, 380, and 540 mAh g⁻¹ for pristine, Co/SnO₂, and Co-N/SnO₂ electrodes, respectively, which means that the phase conversion reaction process of the Co-N/SnO₂ electrode are significantly prolonged during Li storage. This implies that:

Figure 4. XPS spectra of Co/SnO₂ and Co-N/SnO₂ samples: (a) survey profiles and comparisons of Co 2p (b) and N 1s (c) signals.
1) the structural stability of Co-N/SnO₂ electrode is greatly enhanced by the introduction of the Co/N defective states into the SnO₂ lattice and 2) the particle pulverization process of the Co-N/SnO₂ sample is successfully delayed during Li insertion, an important indication of the utilization of the plateau capacity above 0.8 V to avoid SEI formation. Furthermore, the overpotential performance of the Co-N/SnO₂ sample is the smallest one among the three electrodes, which reveals the improvement in electronic/ionic conductivities after Co and N synergistic doping to facilitate Li ion diffusion. On the other hand, the plateau capacity of the Co-N/SnO₂ electrode is about 540 mAh g⁻¹, three times higher with an even lower plateau voltage (0.90 vs. 1.55 V) than that of the Li₅Ti₄O₁₂ spinel anode and much higher without SEI formation than that of the commercialized graphite anode (372 mAh g⁻¹), making it a promising application for LIBs.

CV measurements were carried out to further clarify the origin of the excellent electrochemical performances of the Co-N/SnO₂ electrode. Figure 5b,c, and d show the CV curves of the first four cycles of SnO₂, Co/SnO₂, and Co-N/SnO₂ electrodes at a scanning rate of 0.1 mV s⁻¹. For all three electrodes, during the first cathodic scanning, the cell exhibits a sharp peak potential at approximately 0.90 V, which corresponds to the structural deterioration of SnO₂ and the relevant electrolyte decomposition as well. A small cathodic peak at about 0.51 V can be ascribed to the formation of an SEI film, originating from electrolyte decomposition, which is mainly comprised of polymers and insoluble inorganic by-products. It is clearly shown in Fig. 5b,c, and d that the prominent reduction peaks at about 0.50 V are evidences of the excess formation of SEI film for the Co-N/SnO₂ electrode, which is probably related to its largest specific surface area (Table S1) and the initial irreversible capacity analysis (Fig. 5a). The structure collapse of SnO₂ leads to the formation of amorphous Li₂O matrixes according to the following conversion reaction: SnO₂ + x Li⁺ + xe⁻ → Sn⁶⁺ + 2 Li₂O. Further, the reversibility of this conversion reaction is still under dispute and needs more precise clarification in the future. The presence of peak potential at
about 0.21 V is associated with the alloying reaction in the form of Sn\(^0 + x \text{Li}^+ + x \text{e}^- \rightarrow \text{Li}_x\text{Sn}, 0 \leq x \leq 4.4\), which is attested to be highly reversible during the electrochemical charge/discharge process\(^{39}\). During the anodic scan, the peak potential at 0.50 V corresponds to the de-alloying reaction of Li\(_2\)Sn products. The formation of large clusters possibly leads to the cracking of electrodes and eventually causes an increase in the contact resistance. In addition, oxidation of metallic Sn\(^0\) into SnO and further into SnO\(_2\) could occur when the upper cut-off potential exceeds 800 mV\(^{39}\). Nevertheless, the capacities resulting from the oxidations of Sn\(^0\) to Sn\(^2\) and Sn\(^4\) are found to be very small in proportion to the alloying/de-alloying region (in Fig. 5b–d) (Li\(_2\)Sn ↔ Sn\(^0\) + Li\(_2\)O ↔ SnO ↔ SnO\(_2\)).

The observed CV profiles are consistent with our previous work\(^{23}\) and that of Dahn et al.\(^{40,41}\).

The fitting results give de-alloying peak widths (FWHM) of 0.271, 0.253, and 0.215 V for pure SnO\(_2\), Co/SnO\(_2\), and Co-N/SnO\(_2\) electrodes, respectively. It is clear that the FWHM value for the Co-N/SnO\(_2\) electrode is smaller than those of the Co/SnO\(_2\) and pure SnO\(_2\) electrodes, which proves that the Co and N co-doping accelerates the electrode reaction process\(^{19,20}\). As observed in Fig. 5b–d, the other oxidation/reduction peaks also display the same kind of regularity, which helps to explain the superior rate capability of the Co-N/SnO\(_2\) electrode. On the other hand, it is widely accepted that the difference between redox pairs (D-value) relates to the degree of polarization\(^4\). Table 2 compares the D-values of pristine, Co/SnO\(_2\) and Co-N/SnO\(_2\) electrodes for each alloying/de-alloying redox in the first four cycles. It can be seen that the D-values of the Co-N/SnO\(_2\) electrodes are smaller than those of the pristine and Co/SnO\(_2\) electrodes, implying that Co and N co-doping effectively decreases the electrode polarization upon cycling.

Figure 5e demonstrates the capacity retentions of pure SnO\(_2\), Co/SnO\(_2\), and Co-N/SnO\(_2\) electrodes at 0.1 C. Undoubtedly the electrode of phase-pure SnO\(_2\) exhibits fast capacity decay, the discharging capacity of which deteriorates from 1215 to 118 mAh g\(^{-1}\) after 50 cycles. In contrast, Co doping and Co/N co-doping can effectively enhance the cycling stability of the SnO\(_2\) electrode with which the Co-N/SnO\(_2\) electrode shows obviously optimized electrochemical performance. Specifically speaking, the Co-N/SnO\(_2\) electrode delivers the highest charging capacity of 1152 mAh g\(^{-1}\) in the first cycle, which experiences a gradual capacity decrease within the subsequent 25 cycles. Afterwards, it remains almost the same, with a high capacity of about 700 mAh g\(^{-1}\) until the 50th cycle (Fig. 5e), the capacity of which is significantly higher than the reported ones\(^{18,19}\).

After 50 galvanostatic cycles, the rate capabilities of the same electrodes are further evaluated as shown in Fig. 5f. Under the high current densities of 0.2, 1 and 5 C, the Co-N/SnO\(_2\) electrode could still exhibit desirable capacities of 646, 587, and 557 mAh g\(^{-1}\), much higher than the theoretical capacity of a commercialized graphite anode (372 mAh g\(^{-1}\)). After 90 cycles at various rates ranging from 0.1 to 5 C, a high capacity of 683 mAh g\(^{-1}\) could be achieved in the 100th cycle back at 0.1 C, about a 95.4% retention of the capacity at the 50th cycle. This also shows the good cyclability of the Co-N/SnO\(_2\) electrode. Taking this discussion into account, the remarkably improved electrochemical performances of SnO\(_2\) after Co/N co-doping, as shown in Fig. 5e and f, can be attributed to a short diffusion path, high crystallization, and good electronic conductivity, as well as the buffering effect of doped Co and N ions in the rutile SnO\(_2\) lattice.

To elucidate more details to the electrode kinetics process, EIS measurements were carried out using half cells consisting of pure SnO\(_2\), Co/SnO\(_2\), and Co-N/SnO\(_2\) as working electrodes at the state of open circuit voltage (OCV) as demonstrated in Fig. 6. An equivalent circuit (inset of Fig. 6) was used to analyze the obtained impedance spectra. The intercept at the Z\(_\text{real}\) axis at high frequency corresponds to the ohmic resistance (R\(_s\)), which represents the total resistance of the electrolyte, separator, and electrical contacts. The semicircle in the middle frequency range indicates the charge transfer resistance (R\(_ct\)), and the slope region in the low-frequency range represents the Warburg impedance. For more detail, the fitted resistances through the equivalent circuit (Fig. 6) are listed in Table 3. It can be clearly observed that the solution resistances are similar among the three electrodes. Nevertheless, the charge transfer resistance and Warburg impedance are distinctly different among them. The transfer resistance and Warburg impedance are at minimum values of 137.72 and 172.91 Ω for Co-N/SnO\(_2\) electrode, which are contributed by the co-doping of Co and N into the SnO\(_2\) nanocrystals.

The conductivity of electrode materials can be calculated with respect to the EIS spectra based on previous reports\(^{43,44}\), which are derived in the following equation:

\[
\sigma = \frac{L}{RS}
\]  

(1)

where the parameters \(\sigma\), L, R, and S represent conductivity, thickness of the electrode materials (45 \(\mu\)m), resistance, and sectional area of the electrode materials (64 mm\(^2\)), respectively. The value of \(R_s\) corresponds to the electronic conductivity and that of W, relates to the ionic conductivity, while the total resistance corresponds to the total conductivity. As shown in Table 3, \(\sigma\) is electronic conductivity, \(\sigma_e\) is the ionic conductivity, and \(\kappa\) is defined as the total conductivity of the electrode material. The electric conductivity of the pristine material is 4.04 \(\times\) 10\(^-5\) Ω\(^{-1}\) cm\(^{-1}\), numerically close to that in a previous report\(^{23}\), which confirms that our calculation method is reasonable and acceptable. Obviously, the electric conductivity and ionic conductivity of the Co-N/SnO\(_2\) electrode are 4.07 \(\times\) 10\(^-5\) and 3.64 \(\times\) 10\(^-5\) Ω\(^{-1}\) cm\(^{-1}\), respectively, 

| Cycle number | Redox potential/V | D-Value/Va |
|--------------|-------------------|------------|
|              | Pristine | Co/SnO\(_2\) | Co-N/SnO\(_2\) | Pristine | Co/SnO\(_2\) | Co-N/SnO\(_2\) |
| 1st          | 0.52/0.19 | 0.53/0.18 | 0.51/0.21 | 0.33 | 0.35 | 0.30 |
| 2nd          | 0.52/0.18 | 0.52/0.18 | 0.48/0.22 | 0.34 | 0.34 | 0.26 |
| 4th          | 0.50/0.17 | 0.51/0.19 | 0.47/0.23 | 0.33 | 0.32 | 0.24 |

Table 2. Redox potentials and D-values of pristine, Co/SnO\(_2\) and Co-N/SnO\(_2\). \(^{a}\)D-value: difference between redox pairs.
and $2.24 \times 10^{-5} \, \frac{\Omega^{-1}}{\text{cm}^{-1}}$, much higher than those of the Co/SnO$_2$ and pure SnO$_2$ electrode as shown in Table 3. These results are also in turn to support the improved rate capability of the Co-N/SnO$_2$ composite since the charge transfer process is the rate-determining step for conversion reactions$^{45}$. To further elucidate the mechanism of significantly improved electrochemical properties of the Co and N co-doped material, HRTEM is employed to get deep insight into the microstructure evolution at different discharge/charge states. To simplify the observation, the naked Co-N/SnO$_2$ powder is used as electrode to assemble cells for cycling. The results by HRTEM observation for the cycled Co-N/SnO$_2$ electrodes are shown in Fig. 7. From Fig. 7a, the previous well-crystallized big Co-N/SnO$_2$ nanocrystals (~30 nm or larger in Table 1 and Fig. 3) become much smaller after a discharge process to 0.005 V. It can be clearly observed that the pulverization of Co-N/SnO$_2$ particles upon lithiation introduces many small ordered domains. The measured d-spacings of ordered domains are 3.07, 2.47 Å, 2.47 Å, 2.47 Å, and 2.47 Å, respectively. These results supply solid evidences for: 1) the Li storage mechanism of first phase conversion (Li$_2$O + Sn) and then the alloying reaction (Li$_x$Sn) in SnO$_2$ electrode; 2) the dispersive distributions of Li-Sn alloys or the intermediate product of Sn nanoparticles into the Li$_2$O matrixes, as well as the same conditions for doped Co particles, and 3) the formation of Li$_3$N, a good Li ion conductor (approximately $10^{-3} \, \frac{\text{S}}{\text{cm}}$), which probably comes from the doped N reacting.
with the inserted Li upon lithiation and obviously have a positive influence on the Li ion transport. Further Fig. 7b shows the HRTEM images of delithiated Co-N/SnO2 sample after a reverse charging process to 3.0 V. It can be clearly observed that five kinds of interplanar distances (3.08, 2.48, 3.99, 2.86 and 3.78 Å) are detected in Fig. 7b, which are respectively indexed to the (100) plane of Li3N, (101) plane of Li2O, (101) plane of Sn, (200) plane of Sn and (112) plane of SnO (JCPDS card No. 88-0287). These results undoubtedly support that the final charging product the SnO2 electrode is apt to SnO nanoparticles and the further oxidation of Sn2+ to Sn4+ probably becomes much more difficult without any energy gain. Based on the widely accepted reaction mechanism of SnO2 electrode, it is not surprising to observe the existence of Li2O, Sn, and Li-Sn in the discharged state and Li2O, Sn and SnO in the charged state, which are in accordance with the CV analysis of Fig. 5d. Due to its poor decomposing kinetics in LIBs, the d-spacing of the new product of Li,N, still can be found even at 3.0 V during the charging of SnO2 electrode at the rate of C/10, which is in consistence with the previous reports46–49. Thus in turn, the dispersed Li,N herein contributes a lot to the Li ion diffusion kinetic of the whole Co-N/SnO2 electrode of in electrochemical cycling. This should play an important role in promoting the ionic conductivity and rate performance of Co-N/ SnO2 electrode as discussed previously in Fig. 5f and Table 3.

Conclusions
In summary, the Co-N doped SnO2 nanocrystals have been synthesized and further employed as anode to investigate the Li storage properties for LIBs. The as-prepared Co and N co-doped sample exhibits better capacity retention and rate capability compared with pure and Co doped materials. The excellent electrochemical performances can be attributed to the synergistic effects of 1) reduced particle size and buffering effect of the doping elements Co and N to afford the volume change during cycling and 2) increases in the crystallinity, BET surface area, pore diameter and conductivity to facilitate the diffusion of lithium ions. As a result, this Co-N/SnO2 nanocrystal electrode demonstrates significantly improved cycleability and rate performance. These findings provide significant guidance for designing anode materials with higher reversible capacities for LIBs. Moreover, this approach could be widely applied to large-scale production of nanostructured powders with various compositions and a wide variety of applications.

Experimental Material Synthesis. The synthesis of the Co/SnO2 samples was performed using water as a solvent, starting from SnCl4 · 5H2O, Co(NO3)2 · 6H2O and NaOH. Typically, 20 ml of SnCl4 (4 mmol) and Co(NO3)2 (0.24 mmol) solution was added to 20 ml of NaOH (28 mmol) with vigorous stirring (Co/SnO2 = 6/100 wt.%). The obtained solution was then transferred into a 50 ml Teflon-lined autoclave and maintained at 180 °C for about 12 h. Afterward, the flaxen precipitation was collected, washed with deionized water and ethanol to remove impurities, and subsequently dried in a vacuum oven at 70 °C. The phase pure SnO2 nanocrystal was obtained through the annealing treatment at 350 °C in air for 4 h. An intermediate Co/SnO2 nanocomposite was prepared via a similar method by replacing NaOH with Co(NO3)2, followed by calcination at 350 °C in air for 4 h. The Co/SnO2 electrodes were prepared by spreading a slurry of 90 wt.% active material (SnO2, Co/SnO2, Co-N/SnO2), 10 wt.% acetylene black (Super-P, MMM Carbon), and 10 wt.% binder (polyvinylidene fluoride, PVDF) dissolved in N-methyl-pyrrolidine (NMP) onto the copper foil. After being thoroughly dried, the films were cut into squares with 8 mm in length as working electrodes. The corresponding loading weight was about 1.6 mg cm−2. The electrolyte was 1 M LiPF6 dissolved in a mixture of ethylene carbonate (EC) and dimethyl carbonate (DMC) with a volume ratio of 1:1. The assembly process was conducted in an argon-filled glove-box with the content of H2O and O2 less than 1 ppm.

Gavalnostatic cycling was measured on a battery charger (LAND BT1-10, China) between 0.005 and 3.0 V (vs. Li/Li+) at 0.1 C. Cyclic voltammetry (CV) profiles were performed on an electrochemical workstation with a three-electrode system (CHI660D, Shanghai Chenhua). The CV curves were recorded between 0.005 and 3.0 V at a scanning rate of 0.1 mV s−1. Electrochemical impedance spectroscopy (EIS) measurements were performed over a frequency range from 100 kHz to 10 mHz.

Physical Characterizations. X-ray diffraction (XRD) patterns were recorded on a DX-2500 diffractometer (Fangyuan, Dandong) with Cu Kα radiation of λ = 0.154145 nm. The Raman spectra were collected on a laser Raman spectrometer (RM-1000, Renishaw) with a 633 nm He-Ne laser. Morphological characterization was carried out by field-emission scanning electron microscopy (FESEM) (JEOL JSM 7001F). Energy dispersive X-ray analysis (EDAX) was applied to determine the element composition and distribution, together with FESEM. The images of high-resolution transmission electron microscopy (HRTEM) were collected on Philips CM200 equipment to investigate the pristine material and electrode microstructures. Nitrogen adsorption measurements were performed on a Micromeritics ASAP 2020 adsorption analyzer. Specific surface areas were calculated by the Barrett-Joyner-Halenda (BJH) method. X-ray photoelectron spectroscopy (XPS) was performed on a Thermo Electron Corporation spectrometer with an Al Kα (1486.6 eV) radiation.

Electrochemical Characterizations. The working electrodes were fabricated by spreading the slurry of 80 wt.% active material (SnO2, Co/SnO2, Co-N/SnO2), 10 wt.% acetylene black (Super-P, MMM Carbon), and 10 wt.% binder (polyvinylidene fluoride, PVDF) dissolved in N-methyl-pyrrolidine (NMP) onto the copper foil. After being thoroughly dried, the films were cut into squares with 8 mm in length as working electrodes. The corresponding loading weight was about 1.64 mg cm−2. The electrolyte was 1 M LiPF6 dissolved in a mixture of ethylene carbonate (EC) and dimethyl carbonate (DMC) with a volume ratio of 1:1. The assembly process was conducted in an argon-filled glove-box with the content of H2O and O2 less than 1 ppm.

Gavalnostatic cycling was measured on a battery charger (LAND BT1-10, China) between 0.005 and 3.0 V (vs. Li/Li+) at 0.1 C. Cyclic voltammetry (CV) profiles were performed on an electrochemical workstation with a three-electrode system (CHI660D, Shanghai Chenhua). The CV curves were recorded between 0.005 and 3.0 V at a scanning rate of 0.10 mV s−1. Electrochemical impedance spectroscopy (EIS) measurements were performed over a frequency range from 100 kHz to 10 mHz.
