On the maximal number of du Val singularities for a K3 surface

Chris Peters

November 10, 2020

Abstract

A complex K3 surface or an algebraic K3 surface in characteristics distinct from 2 cannot have more than 16 disjoint nodal curves.

1 Introduction

It is well known that quartic surfaces can have at most 16 ordinary double points and if this is the case the surface is a (classical) Kummer surface. Indeed, projecting from a double point exhibits the quartic surface as a double cover of the plane branched in a degree 6 curve with at most 15 double points and if there are 15 double points, the branch locus consists of a union of 6 lines in general position and its double cover is a classical Kummer surface as explained in [GH78, p. 774]. For a proof based on affine geometry over the field $\mathbb{F}_2$, see [Nik75]. See also [BHPdV04, Prop. VIII.6.1] where it is assumed that the 16 double points form an “even” set (to be explained below).

The aim of this note is to give a simple proof that any complex K3 surface, algebraic or not, can acquire no more than 16 ordinary double points, a result originally due to V. Nikulin [Nik75, Applications, Cor. 1] who proved this by lattice theoretic methods. Remark that on the minimal resolution of such a surface the nodes give disjoint nodal curves and on a K3 surface these span a negative definite lattice in the Picard lattice, a priori of rank $\leq 20$ (recall that non-algebraic surfaces are allowed) and so it is somewhat surprising that there cannot be more than 16 of them.

The proof is based on coding theory and applies equally well to double points of $A-D-E$ type, i.e. to du Val singularities where a refinement can be given. See Remark 4.7. The idea of using coding theory to obtain bounds on the number of double points goes back to A. Beauville’s article [Bea80] and has been further exploited in A. Kalker’s thesis [Kal86]. Applications of codes to characteristic 2 phenomena of K3 surfaces can be found in I. Shimada’s article [Shi04b].

The proof applies to algebraic as well as non-algebraic complex K3 surfaces. The algebraic nature of the proof ensures that it is also valid for algebraic K3 surfaces in characteristics distinct from 2. See Remark 4.2. In characteristic 2 the result is false: there are supersingular K3 surfaces with 21 nodes. See [Shi04a].
Convention In this note $X$ is a compact complex surface, and in §4 it is a K3 surface. I assume throughout that $H^2(X, \mathbb{Z})$ has no torsion and I consider it as a lattice equipped with the integral pairing induced by the cup product. In that situation the Néron–Severi group $\text{NS}(X)$ is to be considered as a sublattice spanned by the classes of the divisors. This is a primitive sublattice of $H^2(X, \mathbb{Z})$.

If $L$ is an integral lattice and $r \in \mathbb{Q}$, I denote by $L(r)$ the same $\mathbb{Z}$-module as $L$ but with form multiplied by $r$.

Acknowledgments This note materialized thanks to ongoing collaboration with Hans Sterk for which I express my thanks. Email exchange with Daniel Huybrechts and Matthias Schütt is also gratefully acknowledged. Thanks go also to Viacheslav Nikulin who kindly pointed me to his original proof.

2 Codes and lattices

A binary code is a linear subspace of some finite dimensional space $W$ over the field $\mathbb{F}_2$ which I shall identify with $\mathbb{F}_2^n$, $n = \dim W$. A vector $x$ of a code $C$ is also called a word. The number of non-zero coordinates of $x$ is its weight, $w(x)$. The dot-product $x \cdot y = \sum x_jy_j \in \mathbb{F}_2$ of two vectors $x = (x_1, \ldots, x_n)$ and $y = (y_1, \ldots, y_n)$ in $\mathbb{F}_2^n$ defines a non-degenerate symmetric bilinear form and a code is called isotropic if $\rho : \mathbb{Z}^n \to \mathbb{F}_2^n$ a code $C$ lifts to a submodule $\rho^{-1}C$ of $\mathbb{Z}^n$ with $2 \cdot \mathbb{Z}^n \subset \rho^{-1}C \subset \mathbb{Z}^n$. The first inclusion shows that $\rho^{-1}C$ is of finite index in $\mathbb{Z}^n$. It inherits the structure of a lattice from $\mathbb{Z}^n$ equipped with its dot-product. However, it turns out to be more convenient to use a different lattice structure, namely $\mathbb{Z}^n$ equipped with the standard euclidean form scaled by $\frac{1}{2}$, which is $\mathbb{Z}^n\left(\frac{1}{2}\right)$ by the convention I adopted. This leads to the lattice

$$\Gamma_C := \rho^{-1}C \subset \mathbb{Z}^n\left(\frac{1}{2}\right).$$

One easily sees that the new product on $\Gamma_C$ has integral values if and only if $C$ is isotropic. See e.g. [Ebe94] § 1.3.

I shall make use of the so-called Reed–Muller codes whose definition runs as follows. Let $I$ be a finite set of size $N$. Then the functions $I \to \mathbb{F}_2$ form the $\mathbb{F}_2$-vector space $\mathbb{F}_2^I$. Suppose that $I$ itself consists of the points of an $\mathbb{F}_2$-vector space $W$ of dimension $\hat{m}$ so that $N = 2^m$. I order these points as follows. Let $\{e_0, \ldots, e_{m-1}\}$ be a basis for $W$ and identify a point $x = \sum_{j=0}^{m-1} x_j e_j$ with the binary expansion $x = \sum_{j=0}^{m-1} x_j 2^j$ of an integer between $0$ and $2^m - 1$. The natural order gives an ordering of the points of $W$. A function $f$ on $W$ determines a vector $(f_0, \ldots, f_{N-1}) \in \mathbb{F}_2^N$ as follows. First note that a point $x \in W$ determines the unique integer $j = n_x \in \{0, \ldots, N-1\}$ and then I set $f_j = f(x)$. The polynomial functions of degree $k$ on $W$ together with the zero function define a subspace of $\mathbb{F}_2^N$ and this is also the case for polynomial functions of degree $\leq k$. The latter define the $k$-th order Reed–Muller
code $S^{\leq k}(W) \subset \mathbb{F}_q^N$, $N = 2^m$. For an extensive treatment of these codes I refer to [Lin92] Chap. 4.5.

Example 2.1. Take $m = 4$ and $k = 1$. Then $N = 2^4 = 16$ and $S^{\leq 1}(\mathbb{F}_2^4) \subset \mathbb{F}_2^{16}$ is generated by the 4 code words given as the rows of the following $4 \times 16$ matrix together with the vector with all coordinates equal to 1 arising from the constant function 1.

The columns correspond to the binary expansions of the numbers 0, ..., 15 and the rows correspond to the coordinate functions $x_0, x_1, x_2, x_3$:

\[
\begin{pmatrix}
0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\
0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\
0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
\end{pmatrix}
\]  \hspace{1cm} (2)

The code

\[
D_{m+1} := S^{\leq 1}(W)
\]  \hspace{1cm} (3)

is a code of dimension $m+1$ given by the affine linear functions on $W$. One can view it as generated by the code $C_m := S^1 W$, consisting of the linear functions on $W$, together with the constant function 1. This last word has weight $2^m$ while the non-zero weights of $C_m$ are all $2^{m-1}$ since the characteristic function of a hyperplane interpreted as a code word has this weight. So the weights of $D_m$ itself (lowering the index by one) are $0, 2^{m-2}$ and $2^{m-1}$. The code $D_m$ can be characterized as follows:

Lemma 2.2 ([Bea80] §4). Let $C \subset \mathbb{F}_2^n$ be a code of dimension $m$ and with non-zero weights $\geq \frac{1}{2} n$. Then $n \geq 2^{m-1}$ and equality holds if and only if $C \cong D_m$ in which case it only has non-zero weights $\frac{1}{2} n = 2^{m-2}$ and $n = 2^{m-1}$.

I need a further property of the code $D_m$:

Lemma 2.3. Suppose $n > 2^{m-1}$. There is no code in $\mathbb{F}_2^n$ with the property that all coordinate subspaces of $\mathbb{F}_2^n$ of dimension $2^{m-1}$ give a code isomorphic to $D_m$.

Proof. Set $N = 2^{m-1}$. Visualize the code $D_m \subset \mathbb{F}_2^N$ as generated by $(1, ..., 1)$ together with the rows of the $(m-1) \times N$ matrix, say $M$, whose columns are the binary expansions of the numbers $0, ..., m-1$ ordered as in (2) where $m = 5, N = 16$.

Suppose that I have a code with the stated properties. Then it contains at least $(m-1)$ vectors whose first $N$ coordinates form the matrix $M$. I now consider the corresponding vectors in $\mathbb{F}_2^n$ forming a matrix $\tilde{M}$. It suffices to consider the case $n = N + 1$ since the effect of deleting $n - N - 1$ columns from $\tilde{M}$ and a further column from $M$ is the same for all $n \geq N + 1$. Suppose that the last column of $\tilde{M}$ corresponds to the decimal expansion of $k \in [0, ..., N-1]$. Then this column is the same as the $k$-th column $M_k$ of $M$. Form now the $(m-1) \times N$ matrix $M'$ by deleting from $\tilde{M}$ a column $M_\ell$ of the submatrix $M$ with $\ell \neq k$. Since all columns of $M$ are different, there is a row $j$ such that the entry $M_{j\ell}$ of $M_\ell$ is distinct from the entry $M_{jk}$ of $M_k$. This implies that the $j$-th row of the new matrix $M'$ has weight $\frac{1}{2} N \pm 1$ which is a contradiction. Hence there is no such code.
3 Sets of nodal curves on a surface

Let $X$ be a compact complex surface containing a finite set $\mathcal{E} = \{E_1, \ldots, E_n\}$ of disjoint smooth rational curves with $E_i^2 = -2$, $i = 1, \ldots, n$. Such curves are also called nodal curves, since these arise as minimal resolutions of ordinary double points. Let $L = \mathbb{Z}E_1 \oplus \cdots \oplus \mathbb{Z}E_n$ be the abstract lattice with basis the nodal classes, which can be identified with $\mathbb{Z}^n(-2)$. Its dual is given by $L^* = \frac{1}{2}L \cong \mathbb{Z}^n\left(\frac{-1}{2}\right)$. The quotient map $L^* \to L^*/L = \frac{1}{2}L/L \cong \mathbb{F}_2^n$ is just the modulo 2 map $\rho : \mathbb{Z}^n \to \mathbb{F}_2^n$ used to construct lattices from codes (see (1)). Reversing the procedure, one starts with the lattice

$$
N_\mathcal{E} := \text{primitive closure of } L \text{ in } \text{NS}(X),
$$

where $\text{NS}(X)$ is the Néron–Severi lattice of $X$. Since there are inclusions $L \subset N_\mathcal{E} \subset N_\mathcal{E}^* \subset L^* \cong \mathbb{Z}^n\left(-\frac{1}{2}\right)$, setting

$$
C_\mathcal{E} = N_\mathcal{E}/L \subset L^*/L = \mathbb{F}_2^n,
$$

the lattice $N_\mathcal{E}(-1)$ is precisely the inverse image of the code $C_\mathcal{E}$ under the mod 2 map. In other words,

$$
N_\mathcal{E} = \Gamma_C_\mathcal{E}(-1).
$$

Using that $N_\mathcal{E}$ is primitive in the lattice $\text{NS}(X)$, I arrive at an equivalent description of the code $C_\mathcal{E}$, namely

$$
C_\mathcal{E} \cong \ker \left( \mathbb{F}_2^n = \bigoplus_j \mathbb{F}_2 E_j \cong L/2L \xrightarrow{\varphi} L/2N_\mathcal{E} \subset N_\mathcal{E}/2N_\mathcal{E} \subset \text{NS}(X)/2\text{NS}(X) \right).
$$

Here primitivity is used to establish the rightmost inclusion.

The first consequence of this description is a bound for $\dim C_\mathcal{E}$. Since $\text{NS}(X)$ is primitive in $H^2(X, \mathbb{Z})$, the quotient $\text{NS}(X)/2\text{NS}(X)$ injects into $H^2(X, \mathbb{Z})/2H^2(X, \mathbb{Z}) = H^2(X, \mathbb{F}_2)$, a symplectic inner product space in which the image of $\varphi$ is totally isotropic and so has dimension $\leq \frac{1}{2}b_2(X)$. It follows that

$$
\dim C_\mathcal{E} \geq n - \frac{1}{2}b_2(X).
$$

Secondly, using the notion of an "even set of nodal curves", which, I recall, means that the sum of the nodal curves is divisible by 2 in $\text{NS}(X)$, there is a further consequence:

**Lemma 3.1.** Non-zero code words in $C_\mathcal{E}$ correspond to even subsets of disjoint nodal curves, and conversely. More precisely, with $e_1, \ldots, e_n$ the standard basis of $\mathbb{F}_2^n$, the sum $\sum_{i \in \mathcal{E}} e_i$ belongs to the code $C_\mathcal{E}$ if and only if $\sum_{i \in \mathcal{E}} E_i$ is even in $\text{NS}(X)$. The weight of a word in $C_\mathcal{E}$ is the cardinality of the corresponding set.

---

1Here $\oplus$ denotes orthogonal direct sum.
4 Applying coding theory to nodal K3 surfaces

There are severe restrictions on even sets of disjoint nodal curves on a complex K3 surface:

**Lemma 4.1.** Let $X$ be a complex K3 surface containing an even set of $k$ disjoint nodal curves. Then $k = 0, 8$ or $16$. If $k = 8$ the associated double cover is a K3 surface and if $k = 16$ it is a complex torus.

**Proof.** Let $\mathcal{E} = \{E_1, \ldots, E_k\}$ be an even set of double curves on $X$ and from the corresponding double cover. The inverse images of the double curves are exceptional curves and blowing these down results in a minimal surface, say $Y_k$. Since the Euler number of $X$ equals $24$, one calculates easily that $e(Y_k) = 48 - 3k$.

On the other hand, the canonical bundle of $Y_k$ is trivial so that $p_g(Y_k) = 1$ and $c_1^2(Y_k) = 0$. The classification theorem [BHPdV04, Ch. VI, Table 10] then gives two possibilities: $Y_k$ is either a torus or a K3-surface. Combining this with Noether’s formula

$$\frac{1}{12}e(Y_k) = 2 - q(Y_k) = \frac{1}{12}(48 - 3k),$$

gives two possibilities: either $k = 8$ and then $Y_k$ is a K3 surface, or $k = 16$ and then $Y_k$ is a torus. $\square$

**Remark 4.2.** The preceding argument is also valid for algebraic K3 surfaces in characteristic different from $2$ since in that case there are only “classical” Enriques and bi-elliptic surfaces having the same invariants as in characteristic $0$. Compare the table on page 373 of [BH75].

Combining Lemma 3.1, Lemma 2.2 and (6) one deduces:

**Corollary 4.3.** For a set $\mathcal{E}$ of disjoint nodal curves on a complex K3 surface the weights of the associated code are $0, 8$ or $16$. If $\mathcal{E}$ consists of $16$ nodal curves, the associated code $C_{\mathcal{E}}$ is isomorphic to $D_5$ where $D_5$ is the Reed–Muller code $[3]$. If $\mathcal{E}$ consists of $8$ nodal curves the code consists of the line in $\mathbb{F}_2^{16}$ spanned by $(1, \ldots, 1)$.

**Proof.** The first assertion is a direct translation of Lemma 4.1 by Lemma 3.1.

Assume that $\# \mathcal{E} = 16$. The estimate (6) for the code $C_{\mathcal{E}} \subset \mathbb{F}_2^{16}$ states that $m = \dim C_{\mathcal{E}} \geq 16 - \frac{1}{2} \cdot 22 = 5$. Then, since the non-zero weights are $\geq 8$, Lemma 2.2 implies $16 \geq 2^{m-1} \geq 2^4$. Hence, since then equality holds, $C_{\mathcal{E}} = D_5$.

The assertion for $k = 8$ is clear. $\square$

Since the code $D_5$ contains the word $(1, \ldots, 1)$, the sum of all the nodal curves is even and so any set of $16$ disjoint nodal curves on a K3 surface $X$ is an even set. This reproves a result by V. V. Nikulin [Nik75]. Forming the double cover gives a complex two-torus blown up in $16$ points and the quotient by the standard

---

2Indeed, the canonical bundle is trivialized on $X$ by a non-zero holomorphic two-form. On the double cover it lifts as a holomorphic two-form which is non-zero outside the branch locus and descends a holomorphic two-form $\omega$ on $Y_k$, nowhere zero except maybe in the points $p_j$. But a section of a line bundle can at most have zeros along a divisor and so $\omega$ trivializes $K_{Y_k}$. 

---

5
Proposition 4.4. Let $X$ be a complex K3 surface containing a set $\mathcal{E}$ of 16 disjoint nodal curves. Then $\mathcal{E}$ is an even set, and $X$ is the minimal resolution of a Kummer surface. Moreover, the primitive sublattice of $\text{NS}(X)$ spanned by $\mathcal{E}$ is isometric to the lattice $\Gamma_{D_8}(-1)$.

The lattice spanned by 16 disjoint nodal curves on a (desingularised) Kummer surface is also called the Kummer lattice. Its characterization as the abstract lattice $\Gamma_{D_8}(-1)$ makes it possible to show the main result of this note:

Theorem 4.5. A K3 surface cannot contain more than 16 disjoint nodal curves.

Proof. Suppose there is a set $\mathcal{E}$ consisting of $n > 16$ disjoint nodal curves on the surface. A subset of 16 nodal curves define a coordinate subspace of the code $C_{\mathcal{E}} \subset \mathbb{F}_2^n$, which, by Corollary 4.3, must be isomorphic to $D_5$. Lemma 2.3 then implies the result. \qed

Suppose $\tilde{X}$ is a compact complex surface with at most du Val singularities, i.e. double points of type $A_n$-$D_n$-$E_n$. The corresponding lower case letter denoting the number of each type, put

$$\delta(X) = \sum (a_n + e_n) \cdot \left\lfloor \frac{n+1}{2} \right\rfloor + d_n \cdot \left\lfloor \frac{n+2}{2} \right\rfloor,$$

where $X$ is the minimal resolution of singularities of $\tilde{X}$. The number $\delta(X)$ gives the number of disjoint nodal curves on $X$ coming from desingularizing $\tilde{X}$ and so one finds:

Corollary 4.6. If $X$ is a K3 surface which is the minimal resolution of singularities of a surface having at most du Val singularities, then $\delta(X) \leq 16$.

In particular, $\tilde{X}$ can have at most 16 ordinary nodes, or $A_1$-singularities. More generally, $\delta(X) = 16$ if there are only $A_1$ or $A_2$ singularities, but otherwise it is strictly smaller. For instance, one can have at most four singularities which all are of types $A_{16}, D_8, D_7, E_7$ or $E_8$. Also note the discrepancy with the Milnor number $\mu(X) = \sum n(a_n + d_n + e_n)$. Indeed the more singularities with high Milnor number, the closer $\delta(X)/\mu(X)$ gets to $\frac{1}{2}$.

Remark 4.7. One can say more for specific types of projective K3 surfaces. For instance, a degree 6 K3 surface in $\mathbb{P}^3$, necessarily a complete intersection of a quadric and a cubic, can have no more than 15 double points. See [Kal86].
