Abstract: This paper is concerned with the problem of designing distributed control protocols for network systems affected by delays and disturbances consisting of a first-order polynomial component and a residual signal. Specifically, we propose the use of a multiplex architecture to design distributed control protocols to reject polynomial disturbances up to ramps and guarantee a scalability property that prohibits the amplification of residual disturbances. For this architecture, we give a sufficient condition on the control protocols to guarantee scalability and ramps rejection. The effectiveness of the result, which can be used to study networks of nonlinearly coupled nonlinear agents, is illustrated via a robot formation control problem.

Keywords: Network systems, delay systems, scalability of networks, stability of nonlinear systems, disturbance rejection.

1. INTRODUCTION

Over the last few years, network systems have considerably evolved, increasing their size and complexity of their topology. The study of coordinated behaviours, such as consensus and synchronization, has therefore attracted much research attention (di Bernardo et al., 2015; Dörfler and Bullo, 2010). In this context, a key challenge is the design of protocols that do not only guarantee stability (i.e. the fulfillment of the desired, coordinated behavior) but also: (i) ensure rejection of certain classes of disturbances; (ii) guarantee that the network is scalable with respect to disturbances that are not fully rejected, i.e. disturbances that are not rejected are not amplified across the network. We use the word scalability to denote the preservation of the desired properties (to be defined formally in Section 3.1) uniformly with respect to the number of agents. Disturbances can be often modeled as the sum of a polynomial component (Park et al., 2012) and a residual signal, capturing components that cannot be modeled via a polynomial. Motivated by this, we: (1) propose a multiplex architecture (Burbano Lombana and di Bernardo, 2016) with the aim of simultaneously guaranteeing rejection of polynomial disturbances up to ramps and scalability for nonlinear networks affected by delays; (2) give a sufficient condition on the control protocol to assess these properties; (3) illustrate the effectiveness of the result on a formation control problem.

Related works. The study of how disturbances propagate within a network is a central topic for autonomous vehicles. In particular, the key idea behind the several definitions of string stability (Swaroop and Hedrick, 1996) in the literature is that of giving upper bounds on the deviations induced by disturbances that are uniform with respect to platoon size, see e.g. (Knorn et al., 2014; Ploeg et al., 2014; Bessellink and Johansson, 2017; Monteil et al., 2019) for a number of recent results. These works assume delay-free inter-vehicle communications and an extension to delayed platoons can be found in e.g. (di Bernardo et al., 2015). For networks with delay free interconnections, we also recall here results on mesh stability (Seiler et al., 1999) for networks with linear dynamics and its extension to nonlinear networks in (Pant et al., 2002). Leader-to-formation stability is instead considered in (Tanner et al., 2004) and it characterizes network behavior with respect to inputs from the leader. For delay-free, leaderless networks with regular topology, scalability has been recently investigated in (Besselink and Knorn, 2018), where Lyapunov-based conditions were given; for networks with arbitrary topology and delays, sufficient conditions for scalability are given in (Xie et al., 2021) leveraging non-Euclidean contraction, see e.g. (Lohmiller and Slotine, 1998; Wang and Slotine, 2006; Shiromoto et al., 2019) and (Monteil and Russo, 2017) where contraction analysis was first used in the context of platooning. Finally, we recall that in the context of vehicle platooning, the problem of guaranteeing string stability and simultaneously rejecting constant disturbances has been investigated in (Knorn et al., 2014; Silva et al., 2021) and this has led to the introduction of an integral action in the control protocol.

Statement of contributions. We tackle the problem of designing network systems that are both scalable and are also able to reject polynomial disturbances up to ramps. Our main contributions can be summarized as follows: (i) for possibly nonlinear networks affected by delays, we propose a multiplex architecture to guarantee both rejec-
tion of ramp disturbances and scalability (with respect to any residual disturbances) requirements. To obtain our knowledge, this is the first work to introduce the idea of leveraging multiplex architectures for disturbance rejection; (ii) the main result we present, which applies to both leader-follower and leaderless networks, is a sufficient condition guaranteeing the fulfillment of the ramp-rejection and scalability requirements. We are not aware of other results to fulfill these requirements; (iii) the result is then turned into a design guideline and its effectiveness is illustrated on a formation control problem.

2. MATHEMATICAL PRELIMINARIES

Let $A$ be a $m \times m$ real matrix, we denote by $\|A\|_p$ the matrix norm induced by the $p$-vector norm $|\cdot|_p$. The matrix measure of $A$ with respect to $|\cdot|_p$ is defined by $\mu_p(A) = \lim_{n \to 0^+} \frac{|I + hA|_p}{h}$, $h > 0$. Given a piecewise continuous signal $w_i(t)$, we let $\|w_i(\cdot)\|_{L^p} := \sup_{t \geq 0} \|w_i(t)\|_p$. We denote by $I_n$ the $n \times n$ identity (zero) matrix and by $0_{m \times n}$ the $m \times n$ zero matrix. We let $\text{diag}(a_1, \ldots, a_N)$ be a diagonal matrix with diagonal elements $a_i$. Given a generic set $A$, its cardinality is denoted as $\text{card}(A)$. We recall that a continuous function $\alpha : [0, a) \to [0, \infty)$ is said to belong to class K if it is strictly increasing and $\alpha(0) = 0$. It is said to belong to class $K_\infty$ if $\alpha \to \infty$ and $\alpha(r) \to \infty$ as $r \to \infty$. A continuous function $\beta : [0, a) \to [0, \infty]$ is said to belong to class $K\mathcal{L}$ if, for each fixed $s$, the mapping $\beta(r, s)$ belongs to class K with respect to $r$ and, for each fixed $r$, the mapping $\beta(r, s)$ is decreasing with respect to $s$ and $\beta(r, s) \to 0$ as $s \to \infty$.

Our results leverage the following lemma, which can be found in (Xie et al., 2021) and follows directly from (Russo et al., 2010). To state the result we let $\|\cdot\|_S$ denote either, any monotone norm and its induced matrix measure on $\mathbb{R}^N$. In particular, we say a norm $\|\cdot\|_S$ is monotone if for any non-negative N-dimensional vector $x, y \in \mathbb{R}^N$, $x \leq y$ implies that $|x|_S \leq |y|_S$ where the inequality $x \leq y$ is component-wise.

Lemma 1. Consider the vector $\eta := [\eta^T, \ldots, \eta^T]$, $\eta \in \mathbb{R}^n$. We let $|\eta|_{G_j} := \|\eta|_{G_j} \ldots, \|\eta|_{G_j}\|_{G_j}$ with $|\cdot|_{G_j}$ being norms on $\mathbb{R}^n$, and denote by $\|\cdot|_{G_j, H_c(\cdot)} := \|\cdot|_{G_j}\|_{G_j, H_c(\cdot)}$ the matrix norm and measure induced by $\|\cdot|_{G_j}$.

Finally, let: (1) $A := (A_{ij})_{i,j=1}^N \in \mathbb{R}^{n \times n}$, $A_{ij} \in \mathbb{R}^{n \times n}$; (2) $\tilde{A} := (\tilde{A}_{ij})_{i,j=1}^N \in \mathbb{R}^{n \times n}$, with $\tilde{A}_{ij} = \mu_G(A_{ij})$ and $\tilde{A}_{ij} := \|A_{ij}\|_{G_i,j}, \|A_{ij}\|_{G_i,j} := \sup_{|x|_{G_i,j} = 1} |A_{ij}x|_{G_i,j}$; (3) $\hat{A} := (\hat{A}_{ij})_{i,j=1}^N \in \mathbb{R}^{n \times n}$, with $\hat{A}_{ij} := \|A_{ij}\|_{G_i,j}$. Then: (i) $\mu_G(\tilde{A}) \leq \mu_G(\hat{A})$; (ii) $\|\cdot|_{G_j} \leq \|\cdot|_{\tilde{G}_j}$.

We recall here that, if the norms $|\cdot|_{G_j}, |\cdot|_{G_i,j}, |\cdot|_{G_i,j}$ in Lemma 1 are p-norms (with the same p) then $|\cdot|$ is again a p-norm (although defined on a larger space). The next lemma follows from Theorem 2.4 in (Wen et al., 2008).

Lemma 2. Let $u : [t_0 - \tau_{\text{max}}, +\infty) \to \mathbb{R}_\geq 0$, $\tau_{\text{max}} < +\infty$ and assume that

$$D^+ u(t) \leq au(t) + b \sup_{t - \tau(t) \leq t < t} u(s) + c, \quad t \geq t_0$$

with: (i) $\tau(t)$ being bounded and non-negative, i.e. $0 \leq \tau(t) \leq \tau_{\text{max}}$, $\forall t$; (ii) $u(t) = \varphi(t), \forall t \in [t_0 - \tau_{\text{max}}, t_0]$ where $\varphi(t)$ is bounded in $[t_0 - \tau_{\text{max}}, t_0]$; (iii) $a < 0$, $b \geq 0$ and $c \geq 0$. Assume that there exists some $\sigma > 0$ such that $a + b \leq -\sigma < 0$, $\forall t \geq t_0$. Then:

$$u(t) \leq \sup_{t_0 - \tau_{\text{max}} \leq s \leq t_0} u(s) e^{-\lambda(t - t_0)} + \frac{c}{\sigma},$$

where $\tilde{\lambda} := \inf_{t \geq t_0} \{\lambda(t) + a + be^{\lambda(t)\tau(t)} = 0\}$ is positive.

3. STATEMENT OF THE CONTROL PROBLEM

We consider a network system of $N > 1$ agents with the dynamics of the $i$-th agent given by

$$\dot{x}_i(t) = f_i(x_i, t) + u_i(t) + d_i(t), \quad t \geq t_0 \geq 0,$$

with $i = 1, \ldots, N$, initial conditions being $x_i(t_0)$ and where: (i) $x_i(t) \in \mathbb{R}^n$ is the state of the $i$-th agent; (ii) $u_i(t) \in \mathbb{R}^n$ is the control input; (iii) $d_i(t) \in \mathbb{R}^n$ is an external disturbance signal on the agent; (iv) $f_i : \mathbb{R}^n \times \mathbb{R} \to \mathbb{R}^n$ is the intrinsic dynamics of the agent, assumed to be smooth. We consider disturbances of the form:

$$d_i(t) = w_i(t) + d_i^0(t) := w_i(t) + d_i^0 + d_{i,1}, \quad t \geq t_0,$$

where $w_i(t)$ is a piecewise continuous signal and $d_i^0, d_{i,1}$ are constant vectors. Disturbances of the form (2) can be thought of as the superposition of the ramp disturbance $d_{i,1}(t) := d_{i,0} + d_{i,1} t$ and the signal $w_i(t)$. In the special case when $d_{i,1}$ is zero, (2) becomes $d_i(t) = w_i(t) + d_{i,0}$ and scalability properties with respect this disturbance have been studied in the context of vehicle platooning (in (Silva et al., 2021)). The term $d_{i,0}$ models the constant disturbance to the acceleration when the vehicle hits a slope and the residual term $w_i(t)$ models the small bumps along the slope. We build upon this and consider disturbance of the form (2) as ramp disturbances naturally arise in a wide range of applications, see Remark 1. Our goal in this paper is to design the control protocol $u_i(t)$ (in 1) so that the ramp disturbance in (2) is rejected, while ensuring a scalability property of the network system with respect to the residual disturbance $w_i(t)$ (see Section 3.1 for a rigorous statement of control goal). To do so, we propose the multiplex network architecture schematically shown in Figure 1. In such a figure, the bottom layer (i.e. layer 0) consists of the network system (1) and the multiplex layers (layer 1, 2) concur to contribute to the control protocol (3):

![Fig. 1. Schematic representation of our multiplex architecture. Black nodes denote the agents while blue nodes represent the (possible) leaders. Colours online.](image-url)
where \( N_i \) see e.g. (Xie et al., 2021; Lawton et al., 2003), are

**Remark 2.**

and Govindarasu, 2014) where the malicious attack is

\[ x(t) = \begin{bmatrix} x_1(t) \cdots x_N(t) \end{bmatrix}^T \]

when leaders are present, not all the agents are necessarily connected to them. Also, \( x(t) = \begin{bmatrix} x_1(t) \cdots x_N(t) \end{bmatrix}^T \) is the state of the network and \( x_i(t) = \begin{bmatrix} x_1^i(t) \cdots x_M^i(t) \end{bmatrix}^T \) is the state of a group of \( M \) leaders. In (3) we assume that the delay vector \( \tau(t) \) is bounded, i.e. \( \tau(t) \leq \tau_{max}, \forall t \). In what follows, we simply term the smooth coupling functions \( h_{i,k}(\cdot, \cdot) \) as delay-free coupling functions, while the functions \( h_{i,k}^{(\tau)}(\cdot, \cdot) \) are termed as delayed coupling functions. As noted in e.g. (Xie et al., 2021) situations where there is an overlap between delayed and non-delayed communications naturally arise in the context of e.g. platooning, formation control and neural networks. Finally, in (3) we set, \( \forall s \in [t_0 - \tau_{max}, t_0], \forall i = 1, \ldots, N, k = 1, 2, x_i(s) = \varphi_i(s), r_{i,k}(s) = \phi_{i,k}(s) \) with \( \varphi_i(s), \phi_{i,k}(s) \) being continuous and bounded functions in \([t_0 - \tau_{max}, t_0] \).

**Remark 1.** We consider disturbances that consist of a ramp component and a piece-wise continuous component. Ramp disturbances are frequently considered in the literature. See for example (Kim et al., 2010), where observers for these types of disturbances are considered and (Sridhar and Govindarasu, 2014) where the malicious attack is modelled in a close form of (2).

**Remark 2.** Control protocols of the form of (3) arise in a wide range of situations. For example, in the context of formation control typical choices for the coupling functions, see e.g. (Xie et al., 2021; Lawton et al., 2003), are

\[
\begin{align*}
\dot{h}_{i,0}(x(t), x_i(t), t) &= \sum_{j \in N_i} h_{i,j}(x_i(t), x_j(t), t) + \sum_{i \in L_i} h_{i,0}(x_i(t), x_i(t), t), \\
\dot{h}_{i,1}^{(\tau)}(x(t - \tau(t)), x_i(t - \tau(t)), t) &= \sum_{j \in N_i} h_{i,j}^{(\tau)}(x_i(t - \tau(t)), x_j(t - \tau(t)), t) \\
&+ \sum_{i \in L_i} h_{i,1}^{(\tau)}(x_i(t - \tau(t)), x_i(t - \tau(t)), t),
\end{align*}
\]

where \( N_i \) and \( L_i \) denote, respectively, the set of neighbours of the \( i \)-th robot and the set of leaders to which the \( i \)-th robot is connected. In the above expression, the coupling functions model both delayed and delay-free communications between agents and with the leaders. Typically, these functions are of the diffusive type and no multiplex layers are foreseen in the control architecture.

### 3.1 Control goal

We let \( u(t) = [u_1^T(t), \ldots, u_N^T(t)]^T \) be the stack of the control inputs, \( d(t) = [d_1^T(t), \ldots, d_N^T(t)]^T \) be the stack of the disturbances, \( w(t) = [w_1^T(t), \ldots, w_N^T(t)]^T \) be the stack of the residual disturbances and \( \tilde{d}(t) = [\tilde{d}_1^T(t), \ldots, \tilde{d}_N^T(t)]^T \) be the stack of the ramp disturbances. We also let \( d_0 = [d_{0,1}, \ldots, d_{N,0}]^T \) and \( d_1 = [d_{1,1}, \ldots, d_{N,1}]^T \). Our control goal is expressed in terms of the so-called desired solution of the disturbance-free (or unperturbed in what follows) network system following (Monteil et al., 2019). Intuitively, the desired solution is the solution of the network system characterized by having: (i) the state of the agents attaining some desired configuration; (ii) the multiplex layers giving no contribution to the \( u_i(s) \). Formally, the desired solution is the solution of network system (1) controlled by (3) such that: (i) \( x^*(t) := [x_1^*(t), \ldots, x_N^*(t)]^T \), with \( x_1^*(t) = f_i(x_1(t), t), \forall i; (ii) r_{i,k}(t) = 0, \forall i, \forall k \) and \( \forall t \).

It is intrinsic in this definition that when the desired solution is achieved it must hold that \( u_i(t) = 0 \) (note that this property is satisfied by e.g. any diffusive-type control protocol). In what follows, for the sake of brevity, we make a slight abuse of terminology and say \( x^*(t) \) is desired solution.

We aim at designing the control protocol (3) so that the closed loop system rejects the ramp disturbances while guaranteeing that the residual disturbances \( w(t) \) are not amplified within the network system. This is captured by the definition of scalability with respect to \( w(t) \) formalized next:

**Definition 1.** Consider the closed loop system (1) - (3) with disturbance \( d(t) = w(t) + \tilde{d}(t) \). The system is \( L_\infty \)-Input-to-State Scalable with respect to \( w(t) \) if there exists class \( \mathcal{K} \) functions \( \alpha(\cdot, \cdot), \beta(\cdot, \cdot), \gamma(\cdot, \cdot) \), a class \( \mathcal{K} \) function \( \gamma(\cdot, \cdot) \), such that for any initial condition and \( \forall t \geq t_0, \max_i |x_i(t) - x_i^*(t)| \leq \]

\[
\max_i \alpha \left( \max_{t_0 - \tau_{max} \leq s \leq t_0} |x_i(s) - x_i^*(s)|, t - t_0 \right) \\
+ \beta \left( \max_{t_0 - \tau_{max} \leq s \leq t_0} |r_{i,1}(s) + \tilde{d}_{i,0} + \tilde{d}_{i,1} \cdot s|_p \right) \\
+ |r_{i,2}(s) + \tilde{d}_{i,1}| \cdot p - t_0 \right) + \gamma \left( \max_i w_i(t) \right) \| w_i(t) \|_{\mathcal{L}_\infty} \right), \forall N. \]

In the special case when \( \tilde{d}(t) = 0 \) and there are no multiplex layers, i.e. \( r_{i,k}(t) = 0, \forall k, \) Definition 1 becomes the definition for scalability given in (Xie et al., 2021). In this context we note that the bounds in Definition 1 are uniform in \( N \) and this in turn guarantees that the residual disturbances are not amplified within the network system. In what follows, whenever it is clear from the context, we simply say that the network system is \( L_\infty \)-Input-to-State Scalable if Definition 1 is fulfilled. In a special case when \( p = 2 \), we use \( L_\infty \)-Input-to-State Scalable for simplicity.

**Remark 3.** With our technical results, we give conditions on the control protocol that ensure scalability of the
closed loop system. Essentially, these conditions guarantee a contractivity property of the network system using G-norm \( |x|_G = \| \sum_{i=1}^N |x_i|_p \|_\infty \).

4. TECHNICAL RESULT

We now introduce our main technical result. For the network system (1) we give sufficient conditions on the control protocol (3) guaranteeing that the closed-loop system affected by disturbances of the form (2) is \( \mathcal{L}_p^\infty \)-Input-to-State Scalable (see Definition 1). The results are stated in terms of the block diagonal state transformation matrix \( T := \text{diag}(T_1, \ldots, T_N) \in \mathbb{R}^{3nN \times 3nN} \) with

\[
T_i := \begin{bmatrix}
I_n & \alpha_{i,1} & 0_n \\
0_n & I_n & \alpha_{i,2} \\
0_n & 0_n & I_n
\end{bmatrix} \in \mathbb{R}^{3n \times 3n},
\]

where \( \alpha_{i,1}, \alpha_{i,2} \in \mathbb{R} \).

**Proposition 1.** Consider the closed-loop network system (1) with control protocol (3) affected by disturbances \( (2) \). Assume that, \( \forall t \geq 0 \), the following set of conditions are satisfied for some \( 0 \leq \sigma < \bar{\sigma} < +\infty \):

\[
\begin{align*}
C1 & \quad h_{i,k}(x^*, x_i, t) = h^{(r)}_{i,k}(x^*, x_i, t) = 0, \forall i, k; \\
C2 & \quad \mu_p(T_i A_i(t) T_i^{-1}) + \sum_{k=1}^p \|T_i A_i(t) T_i^{-1}\|_p \leq \sigma, \forall i \text{ and } \forall x \in \mathbb{R}^{n_x}, \forall x_i \in \mathbb{R}^{n_x} \text{ (the state dependent matrices } A_i(t)'s \text{ are defined in (4))}; \\
C3 & \quad \sum_{j=1}^p \|T_i B_i(t) T_i^{-1}\|_p \leq \sigma, \forall i \text{ and } \forall x \in \mathbb{R}^{n_x}, \forall x_i \in \mathbb{R}^{n_x} \text{ (the state dependent matrices } B_i(t)'s \text{ are also defined in (4))}.
\end{align*}
\]

Then, the system is \( \mathcal{L}_p^\infty \)-Input-to-State Scalable with

\[
\begin{align*}
\kappa_G(T) e^{-\lambda(t-\max)} & \sup_{t_0 - \tau_{\max} \leq s \leq t_0} \|x_i(s) - x_i^*(s)\|_p \\
+ \kappa_G(T) e^{-\lambda(t-\max)} & \sup_{t_0 - \tau_{\max} \leq s \leq t_0} \left( |r_{i,2}(s) + d_{i,1}|_p + |r_{i,1}(s) + d_{i,0} + d_{i,1} \cdot s|_p \right) + \frac{\kappa_G(T)}{\sigma - \bar{\sigma}} \|w_i(\cdot)\|_\mathcal{L}_p^\infty, \forall N,
\end{align*}
\]

where \( \kappa_G(T) := \|T\|_G \|T^{-1}\|_G \), \( \lambda = \inf_{t_0 \geq t_0} \{ \lambda(\lambda(t) - \bar{\sigma}) + \sigma e^{\lambda(t)(t)} \} = 0 \), \( x_i(t) \) is a solution of the agent \( i \) with \( x_i(s) = \varphi_i(s), r_{i,k}(s) = \phi_i(s) \text{ and } x_i^*(s) = x_i^*(t_0) \), \( s \in [t_0 - \tau_{\max}, t_0] \), \( i = 1, \ldots, N \), \( k = 1, 2 \).

**Proof.** We start by augmenting the state of the original dynamics by defining \( z_i(t) := [x_i^T(t), \zeta_{i,1}^T(t), \zeta_{i,2}^T(t)]^T \), and where

\[
\begin{align*}
\zeta_{i,1}(t) &= r_{i,1}(t) + d_{i,0} + d_{i,1} \cdot t, \\
\zeta_{i,2}(t) &= r_{i,2}(t) + d_{i,1}.
\end{align*}
\]

In these new coordinates the dynamics of the network system becomes

\[
\dot{z}_i(t) = \phi_i(z_i(t), t) + v_i(z_i, t) + \tilde{w}_i(t),
\]

where \( \phi_i(z_i(t), t) = [f_i^T(x_i, t), 0_{1 \times n_x}, 0_{1 \times n_x}]^T, \tilde{w}_i(t) = [w_i^T(t), 0_{1 \times n_x}, 0_{1 \times n_x}]^T \), and where

\[
\begin{align*}
v_i(z_i(t), t) &= \begin{bmatrix}
h_{i,0}(x_i(t), x_i(t), t) + h_{i,1}^{(r)}(x_i(t), x_i(t) - \tau(t)), x_i(t) - \tau(t), t) + \zeta_{i,1}(t) \\
h_{i,1}(x_i(t), x_i(t), t) + h_{i,1}^{(r)}(x_i(t), x_i(t) - \tau(t)), x_i(t) - \tau(t), t) + \zeta_{i,2}(t)
\end{bmatrix}.
\end{align*}
\]

Note that C1 implies that the desired configuration \( z_i^*(t) \) is a solution of the unperturbed network dynamics, i.e. \( x_i^*(t) \) satisfies \( \dot{z}_i^*(t) = f_i(z_i^*, t) \). Moreover, when there are no disturbances, in the new set of coordinates, the solution \( z_i^*(t) := [x_i^T(t), 0_{1 \times n_x}, 0_{1 \times n_x}]^T \) satisfies

\[
\dot{z}_i^*(t) = \phi_i(z_i^*, t),
\]

with \( \phi_i(z_i^*, t) = [f_i^T(z_i^*, t), 0_{1 \times n_x}, 0_{1 \times n_x}]^T \). Hence, the dynamics of state deviation \( e_i(t) := z_i(t) - z_i^*(t) \) is given by

\[
\dot{e}_i(t) = \dot{e}_i(t) := \phi_i(z_i^*, t) + v_i(z_i, t) + \tilde{w}_i(t).
\]

Following e.g. (Desoer and Haneda, 1972), we let \( \eta_i(t) = \rho z_i + (1 - \rho) z_i^* \) and \( \eta(t) = [\eta_1^T(t), \ldots, \eta_N^T(t)]^T \) and then rewrite the error dynamics as

\[
\dot{e}_i(t) = A_i(t)e_i(t) + B_i(t)e_i(t - \tau(t)) + \tilde{w}_i(t),
\]

where \( \tilde{w}_i = [\tilde{w}_1^T(t), \ldots, \tilde{w}_N^T(t)]^T \) and \( A \) has entries:

- \( A_{i,j}(t) = J_{i,j}^0(\eta_i(t), t) \) which have entries defined as

\[
\begin{align*}
J_{i,j}^0(\eta_i(t), t) &= \frac{d\eta_i(t, \eta_i(t))}{d\eta_i(t)} \text{ where the superscripts (0) and (r) denote the delay-free and the delayed components of } \eta_i, \text{ respectively.}
\end{align*}
\]

Note, \( \tilde{w}_i(t) = Tz(t) \) and \( e_i(t) := Tz(t) \).

Then, we have

\[
\dot{e}_i(t) = T A_i(t) T^{-1} e_i(t) + T B(t) e_i(t - \tau(t)) + T \tilde{w}_i(t).
\]

Also, taking the Dini derivative of \( e_i(t) \) we obtain

\[
D^+ e_i(t) \leq \mu_G(T A_i(t) T^{-1}) e_i(t) + \|T\|_G \|w_i(\cdot)\|_\mathcal{L}_p^\infty + \|T B(t) T^{-1}\|_G \sup_{t_0 - \tau_{\max} \leq s \leq t_0} \|e_i(s)\|_G.
\]

Next, we find upper bounds for \( \mu_G(T A_i(t) T^{-1}) \) and \( \|T B(t) T^{-1}\|_G \) which allow us to apply Lemma 2. First, we give the expression of the matrix \( A \) (which have entries defined in (4): (i) \( A_{i,j}(t) = J_{i,j}^0(\eta_i(t), t) \) and \( B \) has entries: \( B_{i,j}(t) = J_{i,j}^0(z_i(t), t) \).

Then, by sub-additivity of matrix measures and matrix norms, we get \( \mu_G(T A(t) T^{-1}) \leq \int_0^1 \mu_G(T A(t) T^{-1}) \) and \( \|T B(t) T^{-1}\|_G \leq \int_0^1 \|T B(t) T^{-1}\|_G \) (see also Lemma.

\[
\begin{align*}
A_{i,j}(t) &= \begin{bmatrix}
\frac{\partial f_i(x_i(t), t)}{\partial x_i} & + \frac{\partial h_{i,0}(x_i(t), x_i(t), t)}{\partial x_i} & I_n & 0_n \\
\frac{\partial h_{i,1}(x_i(t), x_i(t), t)}{\partial x_i} & 0_n & I_n & 0_n \\
\frac{\partial h_{i,2}(x_i(t), x_i(t), t)}{\partial x_i} & 0_n & 0_n & 0_n
\end{bmatrix}, B_{i,j}(t) &= \begin{bmatrix}
\frac{\partial J_{i,j}^0(x_i, t)}{\partial x_i} & 0_n & 0_n \\
\frac{\partial J_{i,j}^0(x_i, t)}{\partial x_i} & 0_n & 0_n \\
\frac{\partial J_{i,j}^0(x_i, t)}{\partial x_i} & 0_n & 0_n
\end{bmatrix}
\end{align*}
\]

(4)
3.4 in (Russo and Wirth, 2021)). Moreover, from Lemma 1 it then follows that

\[ \mu_G(T\tilde{A}(t)T^{-1}) \leq \max_i \left\{ \mu_p(T_i\tilde{A}_{ii}(t)T_{ii}^{-1}) + \sum_{j \neq i} \|T_i\tilde{A}_{ij}(t)T_j^{-1}\|_p \right\} \]

and

\[ \|TB(t)T^{-1}\|_G \leq \max_i \left\{ \sum_j \|T_iB_{ij}(t)T_j^{-1}\|_p \right\} , \]

Condition C2 and C3 yields that

\[ \max_i \left\{ \mu_p(T_i\tilde{A}_{ii}(t)T_{ii}^{-1}) + \sum_{j \neq i} \|T_i\tilde{A}_{ij}(t)T_j^{-1}\|_p \right\} \leq -\sigma \]

and

\[ \max_i \left\{ \sum_j \|T_iB_{ij}(t)T_j^{-1}\|_p \right\} \leq \sigma \]

for some \( 0 \leq \sigma < \bar{\sigma} < +\infty \). This implies that \( \mu_G(T\tilde{A}(T)T^{-1}) + \|TB(t)T^{-1}\|_G \leq \bar{\sigma} + \sigma := -\sigma \) and Lemma 2 then yields

\[ |\tilde{e}(t)|_G \leq \sup_{t_0 - \tau_{\text{max}} \leq s \leq t_0} |\tilde{e}(s)|_G e^{-\bar{\lambda}(t-t_0)} + \|T\|_G \max_i \|\tilde{w}_i(\cdot)\|_{\mathcal{L}_\infty} , \]

with \( \bar{\lambda} \) defined as in the statement of the proposition. Since \( \tilde{e} = Te \) we get \( |e(t)|_G \leq \|T^{-1}\|_G |\tilde{e}(t)|_G \) and \( |e(t)|_G \leq \|T^{-1}\|_G |e(t)|_G \). We also notice that the definition of \( w_i(\cdot) \) implies that \( \|\tilde{w}_i(\cdot)\|_{\mathcal{L}_\infty} = \|w_i(\cdot)\|_{\mathcal{L}_\infty} \). Hence

\[ |e(t)|_G \leq \|T^{-1}\|_G |e(t)|_G \sup_{t_0 - \tau_{\text{max}} \leq s \leq t_0} |\tilde{e}(s)|_G e^{-\bar{\lambda}(t-t_0)} + \|T\|_G \max_i \|w_i(\cdot)\|_{\mathcal{L}_\infty} . \]

We note that

\[ |e_i(t)|_p = \left| \begin{array}{c} x_i(t) - x_i^*(t) \\ \cdot G_1(t) \\ \cdot G_2(t) \end{array} \right|_p \leq \left| \begin{array}{c} x_i(t) - x_i^*(t) \\ 0 \times 1 \\ 0 \times 1 \end{array} \right|_p , \]

\[ |e_i(t)|_p \leq \left| \begin{array}{c} x_i(t) - x_i^*(t) \\ 0 \times 1 \\ 0 \times 1 \end{array} \right|_p + \left| \begin{array}{c} \cdot G_1(t) \\ 0 \times 1 \\ 0 \times 1 \end{array} \right|_p \leq \left| \begin{array}{c} x_i(t) - x_i^*(t) \\ \cdot G_1(t) \\ \cdot G_2(t) \end{array} \right|_p . \]

Hence, \( |x_i(t) - x_i^*(t)|_p \leq |e_i(t)|_p \leq |e_i(t)|_p + |e_i(t)|_p \leq |x_i(t) - x_i^*(t)|_p + |\tilde{G}_1(t)|_p + |\tilde{G}_2(t)|_p \). We then finally obtain the upper bound of the state deviation

\[ \kappa_G(T)e^{-\bar{\lambda}(t-t_0)} \max_i \sup_{t_0 - \tau_{\text{max}} \leq s \leq t_0} |x_i(s) - x_i^*(s)|_p + \kappa_G(T)e^{-\bar{\lambda}(t-t_0)} \max_i \sup_{t_0 - \tau_{\text{max}} \leq s \leq t_0} |r_{i,2}(s) + \tilde{d}_{i,1}|_p + |r_{i,1}(s) + \tilde{d}_{i,0} + \tilde{d}_{i,1} \cdot s|_p + \kappa_G(T) \max_i \|w_i(\cdot)\|_{\mathcal{L}_\infty} , \forall N . \]

\[ \text{Remark 4.} \ C1 \ implies \ that \ u_i(t) = 0 \ at \ the \ desired \ solution. \ This \ rather \ common \ condition \ (see \ e.g. \ (di \ Bernardo \ et \ al., \ 2015; \ Xie \ et \ al., \ 2021)) \ guarantees \ that \ x^*(t) \ is \ a \ solution \ of \ the \ unperturbed \ dynamics. \ C2 \ gives \ an \ upper \ bound \ on \ matrix \ measure \ of \ the \ Jacobian \ of \ the \ intrinsic \ dynamics \ and \ of \ the \ delay-free \ part \ of \ the \ protocol. \ C2 \ says \ that \ such \ a \ matrix \ measure \ should \ be \ negative \ enough \ to \ compensate \ for \ the \ norm \ of \ the \ Jacobian \ of \ the \ delayed \ part \ of \ the \ protocol, \ whose \ upper \ bound \ is \ given \ in \ C3. \]

\[ \text{Remark 5.} \ The \ convergence \ rate \ \bar{\lambda} \ depends \ on \ \tau_{\text{max}}. \ Indeed, \ for \ a \ given \ set \ of \ fixed \ \bar{\sigma}, \ \bar{\lambda}, \ increasing \ \tau_{\text{max}} \ decreases \ \bar{\lambda}. \ Hence, \ a \ trade-off \ exists \ between \ the \ length \ of \ delay \ and \ the \ convergence \ rate. \ In \ particular, \ \bar{\lambda} = \bar{\sigma} \ when \ \tau_{\text{max}} = 0 \ which \ yields \ the \ results \ in \ (Monteil \ et \ al., \ 2019) \ for \ a \ delay-free \ platoon \ system \ with \ no \ multiplex \ layers. \]

5. APPLICATION

We show the effectiveness of the result by designing a control protocol satisfying the conditions in Proposition 1 so that a network of \( N \) unicycle robots is \( L_\infty \)-Input-to-State Scalable. In particular, we aim at designing a formation where local residual disturbances on one robot are not amplified and the robots in the formation are required to (i) track the reference provided by a virtual leader; (ii) reject polynomial disturbances up to rumps.

Unicycle dynamics. We consider the following dynamics

\[ \begin{align*}
\dot{p}_i^v &= v_i \cos \theta_i + d_{ii}^v(t) , \\
\dot{\theta}_i &= \Omega_i ,
\end{align*} \]

\[ \forall i , \ \text{where the state variables } p_i(t) = [p_i^v(t), p_i^y(t)]^T \text{ is the inertial position and } \theta_i(t) \text{ is the robot heading angle. The control input is denoted as } u_i(t) = [v_i(t), \Omega_i(t)]^T \text{ with } v_i(t) \text{ being the linear velocity and } \Omega_i(t) \text{ being the angular velocity. The disturbances affecting the robots are } d_i(t) = [d_{i,0}^v(t), d_{i,1}^v(t)]^T \text{ where } d_{i,0}^v(t) := d_{i,0}^v + d_{i,1}^v \cdot t + w_i^v(t) \text{ and } d_{i,1}^v(t) := d_{i,0}^v + d_{i,1}^v \cdot t + w_i^v(t) . \text{ We introduce the following compact notation: } w_i(t) = [w_i^v(t), w_i^y(t)]^T , \ d_i(t) = [d_{i,0}^v, d_{i,1}^v]^T + [d_{i,0}^v, d_{i,1}^v]^T . \text{ The constant term } [d_{i,0}^v, d_{i,1}^v]^T \text{ can model, for example in the case of unicycle-like marine robots, the constant speed disturbance caused by the ocean current (Bechlioulis et al., 2017) and the residual term } w_i(t) \text{ models the transient variation of the current. The ramp term } [d_{i,0}^v, d_{i,1}^v]^T \text{ can model, e.g. ramp attack signals (Sridhar and Govindarasu, 2014). Following (Lawton et al., 2003), the dynamics for the robot hand position is given by}
\end{align*} \]

\[ \dot{\eta}_i(t) = \begin{bmatrix} \cos \theta_i & -l_i \sin \theta_i \\
\sin \theta_i & l_i \cos \theta_i \end{bmatrix} \begin{bmatrix} v_i(t) \\
\dot{d}_i(t) \end{bmatrix} , \]

\[ \forall i \text{ where } l_i \in \mathbb{R}_{>0} \text{ is the distance of the hand position to the wheel axis. The dynamics can be feedback linearised by}
\]

\[ u_i(t) = \begin{bmatrix} \cos \theta_i & -l_i \sin \theta_i \\
\sin \theta_i & l_i \cos \theta_i \end{bmatrix}^{-1} \dot{\eta}_i(t) , \]

\[ \text{which yields}
\]

\[ \dot{\eta}_i(t) = v_i(t) + d_i(t) , \ \forall i \text{ Next we leverage Proposition 1 to design } \nu_i(t) \text{ so that network (8) is } L_\infty \text{-Input-to-State Scalable.}
\]

Protocol design. We denote by \( \eta_i \) the hand position provided by a virtual leader. Robots are required to keep a desired offset from the leader (\( \delta_i^\nu \)) and from neighbours (\( \delta_j^\nu \)) while tracking a reference speed from the leader, say \( v_i \). Hence, the desired position of the \( i \)-th robot, \( \eta_i^* \), is picked so that: (i) the robot keeps the desired offsets from
In the above expression, $i$ is connected to and its cardinality is $\bar{\delta}_{ij}$. To this aim, we propose the following control protocol

\[
\begin{align*}
\nu_i(t) &= h_{i,0}(\eta(t), \eta_i(t), t) + h_{i,0}^{(r)}(\eta(t - \tau(t)), \eta_i(t - \tau(t)), t) + v_i(t) + r_{i,1}(t), \\
\dot{r}_{i,1}(t) &= h_{i,1}(\eta(t), \eta_i(t), t) + h_{i,1}^{(r)}(\eta(t - \tau(t)), \eta_i(t - \tau(t)), t) + r_{i,1}(t), \\
\dot{r}_{i,2}(t) &= h_{i,2}(\eta(t), \eta_i(t), t) + h_{i,2}^{(r)}(\eta(t - \tau(t)), \eta_i(t - \tau(t)), t),
\end{align*}
\]

(9)

where the coupling functions $h_{i,k}, h_{i,k}^{(r)} : \mathbb{R}^{2N} \times \mathbb{R}^2 \times \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}^2$ are smooth functions for delay-free and delayed couplings between the robots and the leader of the form:

\[
\begin{align*}
h_{i,0}(\eta(t), \eta_i(t), t) &= k_0(\eta_i - \eta - \delta_{ij}), \\
h_{i,0}^{(r)}(\eta(t), \eta_i(t), t) &= k_0^{(r)} \sum_{j \in \mathcal{N}_i} \psi(\eta_j - \eta_i - \delta_{ij}), \\
h_{i,1}(\eta(t), \eta_i(t), t) &= k_1(\eta_i - \eta - \delta_{ij}), \\
h_{i,1}^{(r)}(\eta(t), \eta_i(t), t) &= k_1^{(r)} \sum_{j \in \mathcal{N}_i} \psi(\eta_j - \eta_i - \delta_{ij}), \\
h_{i,2}(\eta(t), \eta_i(t), t) &= k_2(\eta_i - \eta - \delta_{ij}), \\
h_{i,2}^{(r)}(\eta(t), \eta_i(t), t) &= k_2^{(r)} \sum_{j \in \mathcal{N}_i} \psi(\eta_j - \eta_i - \delta_{ij}),
\end{align*}
\]

with $\psi(x) := \tanh(k^\psi x)$ inspired from (Monteil et al., 2019). In the above expression, $\mathcal{N}_i$ is the set of neighbours that robot $i$ is connected to and its cardinality is bounded, i.e. $\text{card}(\mathcal{N}_i) \leq N, \forall i$. The control gains $k_0, k_1, k_2, k_0^{(r)}, k_1^{(r)}, k_2^{(r)}, k^\psi$ are positive scalars designed next. The desired formation consists of concentric circles with the $k$-th circle having $4k$ robots. A robot on the $k$-th circle is connected to at most $N$ other robots, i.e. the ones immediately ahead and behind on the same circle and the closest robot on circle $k - 1$ (if any). An example of the desired formation with 3 concentric circles is shown in Figure 2 where the reference trajectory is also plotted. Next

![Fig. 2. Reference trajectory of the hand position from the virtual leader and an example of desired formation.](image)

we make use of Proposition 1 to select the control gains so that the robotic network is $L_\infty$-Input-to-State Scalable. In particular, we note that the choice of the control protocol

\[
\begin{align*}
\max_{i} |\eta_i(t) - \bar{\eta}_i(t)| \leq C \left( 0.07 + 0.02t + 0.05 \sin(t) e^{-0.3t} + 0.06 - 0.04t + 0.06 \sin(t) e^{-0.3t} \right),
\end{align*}
\]

(11)

with $w_i(t) = [0.05 \sin(t) e^{-0.3t}, 0.06 \sin(t) e^{-0.3t}]$ is the residual disturbance signal. The delay is set to $\tau(t) = 0.33s$. Figure 3 shows the maximum hand position deviation when the number of robots in the formation is increased. To obtain such a figure, we start with a formation of 1 circle and increase at each simulation the number of circles in the formation to 10 circles. We recorded at each simulation the maximum hand position deviation for each circle and finally plot the maximum deviation on each circle across all the simulations. In accordance with our theoretical predictions, the figure shows that disturbances are not amplified through the network. To further validate the results, we also report in Figure 4 the hand position deviation of all robots when one robot in circle 1 is affected by $d_i(t)$ in (11). As expected, our protocol is able to reject the ramp component of the disturbance and, at the same time, prohibit the amplification of the residual component $w_i(t)$ in (11).

![Fig. 3. Maximum hand position deviation from the desired position as the number of circles increases.](image)

6. CONCLUSIONS

We considered the problem of designing distributed control protocols for network systems affected by delays and disturbances. We proposed to leverage a multiplex architecture so that: (i) polynomial disturbances up to ramps are rejected; (ii) the amplification of residual disturbances

\[
\begin{align*}
\max_{i} |\eta_i(t) - \bar{\eta}_i(t)| \leq C \left( 0.07 + 0.02t + 0.05 \sin(t) e^{-0.3t} + 0.06 - 0.04t + 0.06 \sin(t) e^{-0.3t} \right),
\end{align*}
\]

(11)
is prohibited. We then gave a sufficient condition on the control protocols to guarantee the fulfillment of these properties. The effectiveness of the result was illustrated, via simulations, on the problem of controlling the formation of unicycle robots. Our future work includes extending the multiplex architecture and the results presented here to reject higher order polynomial disturbances.
