Abstract. The failure analysis of reheater tubes were analyzed by means of alloy composition analysis, metallographic structure analysis, mechanical properties analysis and oxide composition analysis. The results showed: The alloy composition meets the requirements of 12Cr1MoV standard. No abnormality was observed in metallographic structure. Mechanical properties qualified. Oxide components are mainly O and Fe. Comprehensive analysis shows that The main reason of reheater tube failure is oxygen corrosion, which caused thinning of the reheater tube wall, leading to leakage accident. Suggestions for subsequent protection are put forward.

1 Introduction

The essence of oxygen corrosion is that the corrosion of iron by dissolved oxygen in water is a kind of electrochemical corrosion. Iron and oxygen form a corrosion battery. The electrode potential of iron is always lower than the electrode potential of oxygen. Therefore, in a ferrite corrosion battery, iron is the anode and is corroded. Dissolved oxygen here acts as a cathode depolarization, which is a factor that causes iron corrosion. It is called oxygen corrosion[1-3]. Oxygen corrosion is a typical ulcer corrosion[4,5]. The diameter of the corroded area is as small as one millimeter and as large as tens of millimeters. The damage of oxygen corrosion to equipment and pipelines is often not discovered in a short period of time. Oxygen corrosion makes the wall of the boiler drum, convection tube bundle, water wall and other pipes thinner and perforated[6], resulting in a serious shortening of the service life of the boiler and threatening the safe operation of the boiler. On the other hand, the corrosion product iron oxide powder enters the steam turbine part with steam. It is adhered to the nozzles and blades of the steam turbine, so that the steam cannot perform work according to the original design conditions. The efficiency of the steam turbine is affected, and the steam consumption increases, which is not conducive to safe operation. Therefore, sufficient attention should be paid to the oxygen corrosion that occurs in the operation of power station boilers. A case of oxygen corrosion failure of reheater tubes in a certain power plant will be analyzed, the reasons for the failure will be explored, and corresponding protection suggestions will be given.

2 Experimental program

The failure characteristics of reheater tubes were observed by macroscopic morphology, and distinguish its failure types. The alloy composition of reheater tube was analysed by a direct reading spectrometer. then the specific composition of the material can be determined of the reheater pipe. Samples were taken from the failed reheater pipes, after grinding, polishing, and corroding, observe and analyze the morphology of the leaking tube through the LSM700 laser confocal microscope and SEM electron microscope. Use an energy spectrometer (EDS) to determine the elemental composition of the corrosion products.

3 Experimental research

3.1. Macroscopic morphology analysis

Figure 1 shows the macroscopic morphology of the failed reheater tube after sampling. Figure 1(a) is the macroscopic appearance of the outer wall of the two reheater tubes. The outer wall of the two reheater tubes has no obvious defects such as swelling or deformation, and the outer wall oxide scale is normal. Dissecting and observing the two pipes, it was found that there was no obvious oxide layer or scaling site on the inner walls of...
the two pipes, but several corrosion pits were observed on the inner walls of the two pipes, as shown in Figure 1(b). The macroscopic morphology of the corrosion pits on the inner wall of the root reheater tube.

![Image](a) The outer morphology of the tube

![Image](b) The inner morphology of the tube

**Figure 1.** Macro morphology of reheater tube

In order to facilitate the observation of the internal morphology and characteristics of the corrosion pits, the two reheater tube corrosion pits were observed with a solid microscope. The morphology is shown in Figure 2. The morphology showed that the corrosion pit of a reheater tube was a stepped ulcer. The corroded surface was covered with reddish brown rust, with a small amount of corrosion products at the bottom, and the texture was relatively loose. The inner wall of the non-corrosive pit is reddish brown and smooth.

### 3.2. Alloy composition analysis

Take a sample of the reheater tube, flatten it and polish it for chemical composition analysis. The test implementation standard is GB/T 4336-2016, and the instrument model is DV-6 quantitative direct-reading spectrometer. The alloy composition analysis results are shown in Table 1. Table 1 also lists the standard range values of the 12Cr1MoV steel in GB/T 5310-2017. It can be seen from comparison that the content of the detected elements meets the requirements of the 12Cr1MoV steel standard.

| Sample No. | C (wt%) | Si (wt%) | Mn (wt%) | P (wt%) | S (wt%) | Cr (wt%) | Mo (wt%) | V (wt%) |
|------------|---------|----------|----------|---------|---------|----------|----------|---------|
| 1#         | 0.10    | 0.20     | 0.55     | 0.010   | 0.004   | 1.01     | 0.26     | 0.20    |
| 2#         | 0.11    | 0.23     | 0.49     | 0.010   | 0.003   | 1.00     | 0.25     | 0.20    |
| 12Cr1MoV   | 0.08-   | 0.17-    | 0.40-    | <0.025  | <0.010  | 0.90-    | 0.25-    | 0.15-   |

### 3.3. Mechanical performance test

Samples were taken from the two sampling tubes where corrosion did not occur, and the tensile properties were tested at room temperature. The test implementation standard is GB/T 228.1-2010 "Metallic Material Tensile Test Part 1: Room Temperature Test Method". The test equipment model is CMT5205 microcomputer-controlled electronic universal testing machine. The test results are listed in Table 2, and the standard value of the normal temperature tensile performance of 12Cr1MoVG in GB/T 5310-2017 "seamless steel tubes and pipes for high pressure boiler" is also listed. Compared with the standard reference value, it can be seen that the normal temperature tensile performance values of the two reheater tubes meet the standard requirements.

| Sample No. | Rm (N/mm²) | Rp0.2 (N/mm²) | A(%) |
|------------|------------|--------------|------|
| 1#         | 530        | 414          | 31   |
| 2#         | 527        | 385          | 32   |
| 12Cr1MoV   | 512        | 421          | 28   |

### 3.4. Metallographic analysis

The metallographic examination was carried out on the cross-sections near the corrosion pits on the inner wall of the 1# and 2# samples, as shown in Figure 3-4. The comparison of the metallographic structure of the two reheater tubes reveals that the pits of the two tubes have similar corrosion morphologies, and there is a layer of visible corrosion products at the bottom of the pits. There were no inter-granular or transgranular microcracks, no obvious decarburization layer and aging, as shown in Figure 3(a) and Figure 4(a).

![Image](a) The corrosion morphology at the edge
In addition, there is no obvious difference between the metallographic structure near the corrosion pit of the reheater tube and the metallographic structure of the matrix, both of which are ferrite and pearlite, with an aging level of 2.5, as shown in Figure 3(b) and Figure 4(b).

Figure 3. Metallographic structure of reheater tube 1# sample

Figure 4. Metallographic structure of reheater tube 2# sample

3.5. SEM and EDS analysis

Figure 5 is the scanning electron microscope (SEM) morphology of the corrosion products at the bottom of the pit of 1# sample. The topography shows that the oxide structure is loose, with holes, and the surface layer is in the form of fine powder. Except for this, no other foreign matter is seen.

Figure 6 is the energy spectrum of the corrosion product of sample 1#. According to the peak value, the main elements in the corrosion product are Fe and O. Comprehensive SEM morphology and EDS results show that the corrosion product of the reheater tube is Fe$_2$O$_3$.

4 Reason analysis and suggestions

It can be seen from the macroscopic appearance that the outer wall of the reheater tube submitted for inspection is relatively smooth, and there is no trace of oxidation or other loss, but the inner wall of the tube is corroded obviously, and there are many ulcer-like corrosion pits. The surface of the corrosion pit is covered with reddish-brown rust, and the inside of the corrosion product is relatively loose. Macroscopically, the corrosion is caused by the expansion of the inner wall of the tube to the outer wall, and the corrosion gradually penetrates the wall of the tube. The microscopic appearance of the two reheater tubes is similar, and the generation mechanism should be the same. The energy spectrum analysis of the tube matrix shows that the material of the reheater tube is 12Cr1MoV, which meets the requirements of the standard. Observation of the morphology of the reheater tube showed that the metallographic structure of the matrix before the corrosion pit was not abnormal. However, there are discontinuous pits in the corrosion front, and a small amount of corrosion products can be seen inside the pits. In addition, there were no other defects such as decarburized layer or microcracks in the bottom structure. The test results of corrosive substances are mainly Fe and O. Based on the above test results, the corrosion characteristics of the failure of the reheater tube are consistent with the oxygen corrosion characteristics\cite{4,6}.

In addition, when observing the on-site environment of the wall reheater tube, it was found that there was water in the tube during the maintenance of the horizontal section. It shows that the vacuum of the system during the shutdown period did not achieve the
expected effect. As a result, wet steam remains in the reheater tube, which condenses into water after cooling. On the other hand, it also shows that air has leaked in, creating a humid environment. As a result, the oxygen content in the tube is much higher than the requirements of the working conditions, which provides sufficient conditions for oxygen corrosion of the reheater tube[7].

The oxygen corrosion mechanism is as follows:

On the one hand, because oxygen is a strong cathode depolarizer, it can absorb electrons from the cathode to form hydroxide ions. This intensifies the corrosion process, destroys part of the iron oxide protective film, and leaks the metal on the inner wall. When the internal metal leaks, it will form a local battery with the oxygen-containing aqueous solution, causing iron to precipitate iron ions Fe$^{2+}$ from the anode. The eluted iron ions Fe$^{2+}$ and OH$^-$ ions form iron hydroxide. Fe(OH)$_2$ is hardly soluble in water and adheres to the metal surface after precipitation.

On the other hand, corrosion products accumulate on the anode in the form of a precipitate, which will inevitably cause a concentration difference between the oxygen concentration in the precipitate and the oxygen concentration in the water covering the surface of the cathode, resulting in an oxygen concentration difference galvanic cell. With the continuous precipitation of Fe(OH)$_2$, the concentration of iron divalent ions in the liquid layer at the anode is significantly reduced, prompting the iron ions on the anode to continue to be transferred into the aqueous solution, that is, the iron as the anode part is quickly dissolved, thereby triggering re-

The inner wall of the heat exchanger tube accelerates corrosion.

Thirdly, because Fe(OH)$_2$ is easy to oxidize, it will be further oxidized by O in water to form Fe(OH)$_3$. Iron hydroxide is insoluble in water and precipitates. The precipitated Fe(OH)$_2$ and Fe(OH)$_3$ are unstable, and a chemical reaction occurs to form stable Fe$_2$O$_3$.

The electrochemical reaction equation is as follows:

\[
\begin{align*}
\text{Fe} & \rightarrow \text{Fe}^{2+} + 2e^- \\
2\text{H}_2\text{O} + \text{O}_2 + 4e^- & \rightarrow 4\text{OH}^- \\
2\text{Fe} + 2\text{H}_2\text{O} + \text{O}_2 & \rightarrow 2\text{Fe(OH)}_2 \\
4\text{Fe(OH)}_2 + \text{O}_2 + 2\text{H}_2\text{O} & \rightarrow 4\text{Fe(OH)}_3 \\
\text{Fe(OH)}_3 + 2\text{Fe(OH)}_2 & \rightarrow \text{Fe}_2\text{O}_3 + \text{H}_2\text{O}
\end{align*}
\]

The oxygen corrosion in the boiler is mainly related to the dissolved oxygen content in the water quality and the pH value of the water quality. The following protective measures should be taken to prevent oxygen corrosion in the boiler:

a) Protective measures should be taken during boiler downtime. Prevent the wet steam in the pipeline from remaining and condense into water after cooling. Prevent air from entering the boiler[8,9].

b) When adding feed water during boiler startup, ensure that the deaerator is working properly, monitoring the oxygen content in the feed water, and preventing oxygen from entering the boiler[10,11].

c) Do a good job of monitoring the water quality and pH value[12], and adjusting the PH value to operate within the boiler's required range to prevent impurity ions from entering.

d) Strengthen the inspection of the reheater tube, conduct regular thickness inspection and swelling inspection, and monitor it to avoid unexpected shutdown accidents.

5 Conclusions

a) The chemical composition and normal temperature mechanical properties of the reheater tube meet the standard requirements, and there is no abnormality in the metallographic structure.

b) The main reason of reheater tube failure is the electrochemical corrosion of dissolved oxygen on the inner wall. The reason for oxygen corrosion is that the residual steam condenses into water and air into the reheater tube during the shutdown of the boiler, resulting in excess oxygen content. Oxygen corrosion rapidly thinned the thickness of the tube wall, which eventually led to leakage of the reheater pipe.
