(Dated: November 28, 2012)

Abstract

The Lifshitz formula is derived by making use of the spectral summation method which is a mathematically rigorous simultaneous application of both the mode-by-mode summation technique and the scattering formalism. The contributions to the Casimir energy of electromagnetic excitations of different types (surface modes, waveguide modes, and photonic modes) are clearly retraced. A correct transition to imaginary frequencies is accomplished with allowance for all the peculiarities of the frequency equations and pertinent scattering data in the complex $\omega$ plane, including, in particular, the cuts connecting the branch points and complex roots of the frequency equations (quasi-normal modes). The principal novelty of our approach is a special choice of appropriate passes in the contour integrals, which are used for transition to imaginary frequencies. As a result, the long standing problem of cuts in the complex $\omega$ plane is solved completely. Inconsistencies of some previous derivations of the Lifshitz formula are traced briefly. For completeness of the presentation, the necessary mathematical facts are also stated, namely, solution of the Maxwell equations for configurations under consideration, scattering formalism for parallel plane interfaces, determination of the frequency equation roots, and some others.

I. INTRODUCTION

It is not overstatement to say that the Lifshitz formula is the basis for practically all the Casimir calculations dealing with the plane boundaries [1]. However, it was recognized in the literature [2–5] that the derivation of this formula in the original paper [6, 7] is very complicated. It proved that especially involved is the transition to the imaginary frequencies when obtaining the Lifshitz formula by deforming the contours of integration in the complex frequency plane. As far as we know, nobody has afterwards succeeded in repeating this part of Lifshitz’ calculations. Furthermore, it was left unclear what are the excitations of electromagnetic field in matter which were taken into account in this formula. Now the latter point becomes important, in particular, in searching for the materials with given properties which are needed for obtaining the wanted characteristics of the Casimir forces.

Later on, the Lifshitz formula was obtained by making use of different methods, namely: the quantum field theory technique in condensed matter physics [8, 9], mode-by-mode summation [1, 3, 4, 10–15], methods of quantized surface modes and quantized Fresnel modes [16–18], scattering formalism [19, 20], local Green functions [21, 22], and so on. In the present paper we propose another derivation of the Lifshitz formula, namely, this formula will be obtained by making use of the spectral summation method. This approach is a mathematically rigorous simultaneous application of both the mode-by-mode summation technique and the scattering formalism. Inconsistencies of some previous derivations of the Lifshitz formula are traced briefly.

Our derivation of the Lifshitz formula includes two steps: First we determine the spectrum of electromagnetic excitations for given boundaries taking into account the material properties of the media under consideration [23]; afterwards, we accomplish the summation of the relevant zero point energies [22, 24, 25] connected with all branches of this spectrum. For description of the electromagnetic fields in matter we shall use the dielectric formalism with allowance for the usual temporal dispersion. In the framework of this approach, one can concentrate attention on the electromagnetic field dynamics, while the dynamics of induced charges and currents is taking into account by introducing the permittivity and permeability \( \varepsilon(\omega), \mu(\omega) \).

1 The electromagnetic field is coupled, through the Maxwell equations, with charges and currents; therefore, one can take, as the dynamic variable, the local displacement of a continuous charged liquid that describes
When determining the spectrum of electromagnetic field, all physically relevant solutions to Maxwell equations should be taken into account. Obviously, such solutions are all squared integrable solutions which belong to the $L_2$ functional space. In addition, this set of solutions should be complete. In rigorous spectral theory of differential operators, the following assertion is proved: the functional space including the solutions which describe the bound states (discrete spectrum branch) and scattering states (continuous branch of the spectrum) is complete with respect to the $L_2$-norm. It is these solutions that we shall find in the problem at hand and on this basis we shall determine the relevant spectrum, i.e. the admissible values of the electromagnetic oscillation frequencies $\omega$. Upon determining the complete set of the solutions to the Maxwell equations, quantization of the electromagnetic field is trivial, because we are dealing here with the sum of two infinite sets (discrete and continuous) of noninteracting oscillators. The discrete set of oscillators describes the evanescent waves including the surface and waveguide modes; and a continuous set of oscillators is responsible for the scattering states. All these modes will be rigorously defined in the course of constructing the complete set of solutions to the Maxwell equations (see below).

The summation of zero point energies of the discrete modes can be accomplished, obviously, in a straightforward way, while for the summation of such energies appertaining to scattering states one has to take advantage of the scattering formalism. Preceding derivations of the Lifshitz formula in the framework of the mode-by-mode summation alone or by making use of the scattering formalism only are apparently inconsistent from the mathematical point of view. Strictly speaking, each of these methods can be applied separately to one branch of the spectrum, namely, the mode-by-mode summation is applicable to discrete part of the spectrum solely and the scattering formalism enables one to take into account the scattering states, i.e. it is applicable to the continuous part of the electromagnetic spectrum only.

The understanding of this fact was absent in previous papers, for example, in Ref. applying the mode-by-mode summation technique it was noted that "... the surface modes

---

2 In the general case, the spectrum of a differential operator may be more complicated. However in the Casimir calculations such problems do not occur.

3 In physical problems dealing with the plane boundaries the surface modes and waveguide modes are called sometimes the guided modes.
alone do not yield right expression” for the correct retarded dispersion force. But the author didn’t find out what should be added to the surface modes in order to obtain correct result. He claimed further that the calculations presented in papers [11, 12] are incorrect because the cuts in the complex frequency plane $\omega$ were not taken into account when applying the argument principle [13, 14]. For solving the problem of branch cuts, it was proposed to consider the plates of a finite thickness instead of semi-infinite slabs [3, 4, 13, 14].

In fact in papers [11, 12] and in many others [1, 13–18], besides neglecting the cuts in the complex frequency plane, that is a mathematical mistake, there is another physical inconsistency, namely the continuous spectrum was completely ignored. The author of Ref. [12] argued erroneously that “...the well-known Lifshitz formula for the retarded van der Waals attraction between two solid half-spaces can be obtained from the zero-point energy of the interacting surface plasmons.” Keeping in mind the well known paper [10], one could make wrong inference that both nonretarded and retarded van der Waals interaction given by Lifshitz formula are due to nonretarded and retarded surface plasmon interactions respectively [32]. Thus it turned out as if the electromagnetic bulk excitations (scattering states) are irrelevant to the calculation of the vacuum forces.

On the other hand, when deriving the Lifshitz formula in the framework of the scattering formalism alone (see, for example, [33]), an artificial technique was applied in order to take into account the evanescent waves (bound states), namely, analytical continuation of the reflection and transition amplitudes to the corresponding region [34].

As a matter of fact, it will be shown in the present paper that all these problems can be solved consistently only by a simultaneous allowance for the contributions to the vacuum energy generated by the evanescent modes (discrete branch of the electromagnetic spectrum) and by the scattering states (continuous part of this spectrum), provided the appropriate mathematical methods will be employed for treating the different parts of the spectrum.

The important step in the Casimir calculations is the transition to the imaginary frequencies. In our opinion this transition was not rigourously justified at least in the framework of the mode-by-mode summation technique. It is this issue that resulted in foregoing confusion and erroneous claims in the first attempts to derive the Lifshitz formula by the mode summation [1, 3, 4, 10, 18]. In order to accomplish this transition in a consistent way the analysis of the analytical properties of the frequency equations and the scattering data in the complex $\omega$ plane should be conducted preliminary and the needed cuts connecting the
branch points in this plane should be done. In the pertinent literature [1–4, 10–22] these issues were not examined. We are going to fill in this gap.

It is worth noting here that the analytic properties of the scattering matrix (or the Jost function) in the Casimir studies are different in comparison with the standard theory of potential scattering. In fact they are close to those for the Klein-Gordon equation, the role of mass squared being played by \( k^2 \), where \( k \) is the wave vector along the unbounded dimensions. This implies, in particular, that the analytic properties of the scattering matrix with respect to the complex frequency \( \omega \) in the Casimir calculations should be revealed by direct analysis of its explicit form without referring to the nonrelativistic potential scattering in the framework of the Schrödinger equation.

The layout of the paper is the following. Section II is devoted to the spectrum of electromagnetic excitations in the problem under consideration. For the Casimir studies the materials permitting the surface waves are of current interest. The permittivity of these media can acquire, in certain frequency bands, negative values. Typical examples of these materials (metals and isotropic dielectrics) are discussed briefly. In Sec. II A the general solutions to the Maxwell equations for plane parallel interfaces are constructed. The both branches of the spectrum are considered in detail. In Sec. III the Lifshitz formula for the Casimir energy is derived by summing up the zero point energies of discrete modes and scattering states. In Sec. IV (Conclusion) the obtained results are summed and unsolved problems in this field are briefly outlined.

II. THE SPECTRUM OF ELECTROMAGNETIC EXCITATIONS

The electromagnetic excitations in the media are diverse, and they essentially depend on the dielectric and magnetic properties of the background.

It is worth mentioning that we are interested in the long wave excitations with \( \lambda \gtrsim d \), where \( d \) is the characteristic scale in the Casimir calculation (\( d \sim 10 – 100 \) nm) and \( \lambda \) is the considered wave length. The description of the condensed matter in terms of the dielectric permittivity assumes the long wave approximation as well.

In applications the dielectric properties of the materials play the leading role, therefore in what follows we put the magnetic permeability equal to a unit.

Of particular interest for theoretical and experimental Casimir studies are the media with
dielectric permittivity taking on negative values over a certain frequency range. Only interfaces of such media support surface electromagnetic waves which can be treated as collective excitations of electron density. The surface waves together with waveguide solutions belong to the discrete branch of the spectrum (see Sec. II B).

Metals are typical media of this sort. The overall picture of the electromagnetic waves (excitations) in metal resembles that in plasma but is not identical with it. In the bulk of the metal the local electron density oscillates with the characteristic plasma frequency

$$\omega^2_p = \frac{4\pi ne^2}{m},$$  \hspace{1cm} (2.1)

where \(n\) is the mean electron density in the metal and \(m\) is the electron mass, the role of the restoring force being played by the electrostatic field. The volume plasma excitations give rise to surface excitations of the electron density (surface plasmons) which propagate along the metal-dielectric or metal-vacuum interface. Obviously, the oscillations of the free charge density cause, according to the Maxwell equations, the oscillations of the electromagnetic field.

For metals, the following dielectric function is commonly used (plasma model)

$$\varepsilon(\omega) = 1 - \frac{\omega^2_p}{\omega^2},$$ \hspace{1cm} (2.2)

where \(\omega_p\) is the plasma frequency (2.1). The dielectric permittivity \(\varepsilon(\omega)\) takes negative values in the region \(\omega < \omega_p\). The field oscillations caused by the surface oscillations of the electron density are localized near the surface as well. They are sometimes called surface plasmons (see the corresponding analysis of the solutions to the Maxwell equations in Section II A).

Inside the metal the bulk waves propagate with the frequencies \(\omega > \omega_p\). The transversal and longitudinal bulk waves form the continuous branch of the spectrum.

In an isotropic dielectric the permittivity is described, with a good accuracy, by an oscillator model \cite{35}. To gain better understanding, one can consider the atoms in a dielectric as weakly damped harmonic oscillators with eigenfrequencies \(\omega_i\) excited by an external electric field \(E = E_0 e^{-i\omega t}\). The \(N\)-oscillator model gives the following dielectric function:

$$\varepsilon(\omega) = \varepsilon(\infty) + \sum_{j}^{N} \frac{S_j \omega^2_j}{\omega^2_j - \omega^2 - i\Gamma_j \omega},$$ \hspace{1cm} (2.3)

where \(S_j\) is the \(j\)-th oscillator strength and \(\Gamma_j\) is its relaxation parameter. In what follows we neglect the absorption (undamped oscillators, \(\Gamma_j = 0\)) and consider real dielectric permittivity. It is negative for \(\omega\) approaching \(\omega_j\) from the right.
Thus, the condition for the existence of the surface plasmon at the flat dielectric-vacuum interface is fulfilled near the narrow absorption lines of the dielectric media. The number of the plasmons in this case is equal to the number of oscillators in the model.

The bulk waves in dielectrics (continuous spectrum) lie in the ranges of frequencies where \( \varepsilon(\omega) \) is positive.

A. General solutions to Maxwell equations

First we recall briefly the formulation of the Maxwell theory for compound media with constant permittivity \( \varepsilon \) and permeability \( \mu \) in each region. In this case, the harmonic in time electric (\( \mathbf{E} \)) and magnetic (\( \mathbf{H} \)) fields are described by the Maxwell equations \[36\]

\[
\nabla \times \mathbf{E} = \frac{i \omega}{c} \mathbf{B}, \quad \nabla \cdot \mathbf{D} = 0, \quad (2.4)
\]

\[
\nabla \times \mathbf{H} = -\frac{i \omega}{c} \mathbf{D}, \quad \nabla \cdot \mathbf{B} = 0, \quad (2.5)
\]

\[
\mathbf{D} = \varepsilon \mathbf{E}, \quad \mathbf{B} = \mu \mathbf{H}, \quad \mathbf{x} \notin \Sigma, \quad (2.6)
\]

which hold outside the interface \( \Sigma \) separating the regions with different \( \varepsilon \) and \( \mu \), and by matching conditions on \( \Sigma \). These conditions require the continuity of tangential components of the fields \( \mathbf{E} \) and \( \mathbf{H} \) when crossing \( \Sigma \)

\[
\text{discont } (\mathbf{E}_\parallel) = 0, \quad \text{discont } (\mathbf{H}_\parallel) = 0. \quad (2.7)
\]

The Gauss units are used and it is assumed that external charges and currents are absent (both volume and surface ones). The common time factor \( e^{-i\omega t} \) will be dropped.

When allowing for the time dispersion, the permittivity \( \varepsilon \) and permeability \( \mu \) in material equations (2.6) and further should be treated as the functions of the frequency \( \omega \).

General solution to Eqs. (2.4), (2.5), and (2.6) can be represented in terms of two independent Hertz vectors in the following way \[36-38\]

\[
\mathbf{E} = \nabla \times \nabla \times \mathbf{\Pi}', \quad \mathbf{H} = -i\varepsilon \frac{\omega}{c} \nabla \times \mathbf{\Pi}' \quad \text{(TM-modes)}; \quad (2.8)
\]

\[
\mathbf{E} = i\mu \frac{\omega}{c} \nabla \times \mathbf{\Pi}'', \quad \mathbf{H} = \nabla \times \nabla \times \mathbf{\Pi}'' \quad \text{(TE-modes)}. \quad (2.9)
\]

Here \( \mathbf{\Pi}' \) is the electric Hertz vector, \( \mathbf{\Pi}'' \) is the magnetic Hertz vector, and \( c \) is the velocity of light in vacuum.
In each region with given $\varepsilon(\omega)$ and $\mu(\omega)$ the Hertz vectors obey the Helmholtz vector equation

$$\left(\nabla^2 + k^2\right) \Pi = 0, \quad (2.10)$$

where the wave number $k$ is given by

$$k^2 = \varepsilon(\omega)\mu(\omega)\frac{\omega^2}{c^2}. \quad (2.11)$$

The boundary conditions (2.7) are given for the complete fields $E$ and $H$, i.e. for the sums of the TE- and TM modes. However, for the interfaces of high symmetry the TE- and TM-modes, fortunately, decouple in (2.7).

It is known that in the source-free case the general solution of Maxwell’s equations can be derived from two real scalar functions $[39, 41]$ which may be chosen in different ways. Thus the Hertz potentials have in fact only one nonvanishing component. The precise choice of these components is determined by the interface geometry and the reasons of simplicity and convenience.

We consider the flat interface parallel to the $(x, y)$ coordinate plane and cutting the $z$-axis at the point $z = z_0$. Let $e_x, e_y, e_z$ be the unit base vectors in the chosen coordinate system. The $z$-components of the Hertz potentials are treated as two independent functions in the general solution to the Maxwell equations

$$\Pi' = e_z e^{ik_s \phi(z)}, \quad \Pi'' = e_z e^{ik_s \psi(z)}. \quad (2.12)$$

Here $k$ is a two-component wave vector parallel to the interface, $\mathbf{k} = (k_x, k_y)$, and $\mathbf{s} = (x, y)$. The common time-dependent factor $e^{-i\omega t}$ is dropped as usual.

Substituting the Hertz potentials (2.12) in (2.8) and (2.9) we get the fields for the TE-modes

$$E = \mu \frac{\omega}{c} k_x e_y e^{iks \psi(z)}, \quad (2.13)$$

$$H = ik_x e_x e^{iks \psi'(z)} + e_z k^2 e^{iks \psi(z)} \quad (2.14)$$

and for the TM-modes

$$E = ik_x e_x e^{iks \psi'(z)} + e_z k^2 e^{iks \phi(z)}, \quad (2.15)$$

$$H = -\varepsilon \frac{\omega}{c} k_x e_y e^{iks \phi(z)}. \quad (2.16)$$
Without loss of generality, we directed the $x$-axis along the vector $\mathbf{k} = (k_x = \pm k, 0)$.

For the fields (2.13)–(2.16) to obey the Maxwell equations (2.4)–(2.6) the Hertz potentials should meet the Helmholtz equation (2.10) which now assumes the form

$$-\Phi''(z) = \left( \varepsilon \mu \frac{\omega^2}{c^2} - k^2 \right) \Phi(z) \quad \text{(TM-modes)},$$

$$-\Psi''(z) = \left( \varepsilon \mu \frac{\omega^2}{c^2} - k^2 \right) \Psi(z) \quad \text{(TE-modes)},$$

$$-\infty < z < \infty, \quad z \neq z_0, \quad k^2 = k_x^2 + k_y^2.$$

Substitution of the fields (2.13)–(2.16) into the continuity equations (2.7) results in the matching conditions at $z = z_0$ separately for the functions $\Phi$ and $\Psi$

$$[\varepsilon(z_0) \Phi(z_0)] = 0, \quad [\Phi'(z_0)] = 0 \quad \text{(TM-modes)},$$

$$[\mu(z_0) \Psi(z_0)] = 0, \quad [\Psi'(z_0)] = 0 \quad \text{(TE-modes)},$$

where the notation

$$[F(z)] \equiv F(z + 0) - F(z - 0)$$

is introduced.

For a given value of $k^2 > 0$ the differential equations (2.17), (2.18) with matching conditions (2.19), (2.20) and physical conditions at infinity $z \to \pm \infty$ result in two spectral problems for the TE and TM polarizations. The frequency $\omega$ plays part of the spectral parameter. For complicated functions $\varepsilon(\omega)$ and $\mu(\omega)$ the spectral parameter may enter into the initial differential equations nonlinearly.

**B. The branches of electromagnetic spectrum relevant for calculation of vacuum energy**

In order to calculate the vacuum energy of the electromagnetic field, one has preliminarily to quantize this field with allowance for given boundary conditions. To this end, the full set of solutions to the Maxwell equations including all physically relevant ones is needed. In the directions parallel to the interfaces the electromagnetic field dynamics is free. Therefore, we are concerned with the behaviour of the solutions normal to the boundaries, along the $z$ axis.
As was mentioned in the Introduction, the full set of physically relevant solutions in the problem under consideration comprises discrete natural modes and scattering states.

Normal modes are the solutions to the Maxwell equations which are localized near and between the interfaces, their energy being localized too. They are analogous to the bound states in quantum mechanics. These solutions are square-integrable on the whole $z$ axis. The corresponding frequencies (the eigenvalues of the spectral problem) take on discrete real values.

The scattering states (propagating modes) are described by incident waves and outgoing scattered (or reflected and transmitted) waves. Their frequencies are real and positive forming a continuous spectrum.

1. Discrete part of the spectrum

We start with considering a single flat interface in order to elucidate the properties of dielectric and magnetic functions required for the existence of normal modes in the problem under study.

a. Normal modes for a single plane interface. Let the plane $z = 0$ separate two uniform half-spaces characterized by $\varepsilon_1, \mu_1$ and $\varepsilon_2, \mu_2$, or symbolically $(\varepsilon_1, \mu_1|\varepsilon_2, \mu_2)$. The general solution to the Maxwell equations are defined by two functions $\Phi(z)$ and $\Psi(z)$ obeying (2.17), (2.18) and the matching conditions (2.19), (2.20). The eigenfunctions in the problem should decrease exponentially in both directions from the interface, i.e. they behave like outgoing waves with imaginary wave-vectors

$$
\Phi(z) = \begin{cases} 
A_1 e^{-ik_1z}, & z < 0, \\
A_2 e^{ik_2z}, & z > 0,
\end{cases}
$$

(2.22)

where $A_1$ and $A_2$ are the constant amplitudes,

$$
k_\alpha^2 = \varepsilon_\alpha \mu_\alpha \frac{\omega^2}{c^2} - k^2 = \frac{\omega^2}{c_\alpha^2} - k^2 < 0, \quad \varepsilon_\alpha^2 = \frac{c^2}{\varepsilon_\alpha \mu_\alpha}, \quad \alpha = 1, 2,
$$

(2.23)

provided that

$$
k_\alpha = +i |k_\alpha|, \quad \alpha = 1, 2.
$$

(2.24)

On substituting (2.22) and the analogous representation for the function $\Psi(z)$ into the matching conditions (2.19) and (2.20) we arrive at the following equations determining the
eigenfrequencies
\[ \varepsilon_1 k_2 + \varepsilon_2 k_1 = 0 \quad \text{(TM-modes)}, \]
\[ \mu_1 k_2 + \mu_2 k_1 = 0 \quad \text{(TE-modes)}. \]

In view of condition (2.24) the frequency equations (2.25) and (2.26) may have real roots (real eigenfrequencies) only if the permittivities \( \varepsilon_1, \varepsilon_2 \) and permeabilities \( \mu_1, \mu_2 \) have different signs.

This condition is fulfilled, for instance, at the metal-vacuum interface, provided the dielectric function of the metal \( \varepsilon_1(\omega) \) is described by the plasma model (2.2). In this case we put \( \varepsilon_2 = \mu_1 = \mu_2 = 1 \). Substituting all this into (2.23) and (2.25), one obtains the dispersion equation for the surface plasmon in the TM-polarization
\[ \Omega^4 - (1 + 2q^2)\Omega^2 + q^2 = 0, \] (2.27)
where the dimensionless variables
\[ \Omega = \frac{\omega}{\omega_p}, \quad q = \frac{k}{k_p}, \quad k_p = \frac{\omega_p}{c} \] (2.28)
are introduced. Solution to Eq. (2.27) is given by
\[ \Omega(q) = \sqrt{\frac{1}{2} + q^2} - \sqrt{\frac{1}{4} + q^4}. \] (2.29)

The dispersion curve \( \Omega(q) \) is presented in Fig. 1a. Another solution to Eq. (2.27) leads to positive \( k_2^t \) that corresponds to propagating waves in medium 1 (dotted curve in the upper-left corner in Fig. 1a). In view of the asymptotic behavior
\[ \Omega(q) \to q \left(1 - \frac{q^2}{2} + \cdots\right), \quad q \to 0, \quad \Omega(q) \to \frac{1}{\sqrt{2}} \left(1 - \frac{1}{8q^2} + \cdots\right), \quad q \to \infty, \] (2.30)
the dispersion curve \( \Omega(q) \) tends in these limits to two straight lines \( \Omega = q \) and \( \Omega = 1/\sqrt{2} \) from below. Here \( \Omega = 1/\sqrt{2} \) is the dimensionless frequency of the surface plasma oscillations (see Fig. 1a).

With \( \mu_1 = \mu_2 = 1 \), obviously, there is no surface modes in the TE-polarization.

The surface waves can be sustained by the dielectric-vacuum interface too, as the dielectric permittivity, with account for the dispersion (2.3), may take on negative values. The corresponding dispersion law can be found, for example, in [42].
Normal modes for two parallel plane interfaces

Now let us consider two interfaces, parallel to the $xy$ plane and cutting the axis $z$ at the points $z = -a$ and $z = a$. For simplicity we consider at first symmetric configuration that can be symbolically represented as

$$(\varepsilon_1, \mu_1 \mid \varepsilon_2, \mu_2 \mid \varepsilon_1, \mu_1).$$

For given polarization, the normal modes can be subdivided into symmetric or asymmetric solutions. Thus, we have for the TM-modes

$$\Phi(z) = \begin{cases} 
A e^{-ik_1(z+a)}, & z < a; \\
B \frac{\cos k_2 z}{\sin k_2 z}, & -a < z < a; \\
\pm A e^{ik_1(z-a)}, & z > a,
\end{cases} \tag{2.31}$$

and the analogous ansatz for the function $\Psi(z)$ in the case of the TE-modes. The wave vectors $k_1$ and $k_2$ in (2.31) are defined, as before, by Eq. (2.23). For $|z| > a$ we again consider the ‘outgoing waves’ with the imaginary wave-vector $k_2^2 < 0$, while in the region $|z| < a$ the wave vector $k_2$ may be both imaginary, $k_2^2 < 0$, or real, $k_2^2 > 0$. In the first case, the waves are just surface ones localized near the interfaces and in the second case, they are the waveguide solutions\textsuperscript{4} describing the standing waves between the interfaces and the evanescent waves outside this region. Indeed, both solutions are normal modes because they are squared integrable on the whole axis $z$.

The matching conditions at the points $z = -a$ and $z = a$ result in the respective frequency equations. For the TM-modes these equations read

$$L_a \equiv ik_1 \varepsilon_2 + \varepsilon_1 k_2 \tan(ak_2) = 0 \quad \text{(asymmetric modes)}, \tag{2.32}$$

$$L_s \equiv ik_1 \varepsilon_2 - \varepsilon_1 k_2 \cot(ak_2) = 0 \quad \text{(symmetric modes)}. \tag{2.33}$$

When defining the spatial symmetry of the electromagnetic modes we follow the papers \cite{43,45}, namely, the symmetric TM-modes are constructed by making use of the symmetric function $\Phi'(z)$ and, consequently, antisymmetric function $\Phi(z)$ in Eqs. (2.15), (2.16). It implies that the longitudinal component of the electric field $E_z(z)$ is symmetric with respect to the plane $z = 0$ and the transverse components of the fields $E_z(z)$ and $H_y(z)$ are antisymmetric. The antisymmetric TM-modes have the contrary symmetry properties, i. e.

\textsuperscript{4} In \cite{33}, such solutions are referred to as the cavity modes.
$E_x(z)$ is antisymmetric with respect to the $z = 0$ plane, and $E_z(z)$ and $H_y(z)$ are symmetric. In the literature \cite{46, 47} reverse notation is used too. The eigenfrequencies of the symmetric modes are denoted by $\omega_s(k)$ and those for the antisymmetric modes by $\omega_a(k)$. In the literature different notation for these frequencies is used, for example, sometimes $\omega^+(k)$ is referred to the higher frequency modes and $\omega^-(k)$ applies to the lower frequency collective oscillations \cite{43, 44}.

By making use of the trigonometric relations

$$
\tan 2x = \frac{2 \tan x}{\tan^2 x - 1} = \frac{2 \cot x}{\cot^2 x - 1},
$$

the frequency equations \eqref{eq:2.32} and \eqref{eq:2.33} can be combined into one equation

$$
\tan(2ak_2) = \frac{-2i\gamma}{1 + \gamma^2}, \quad \gamma = \frac{\varepsilon_2k_1}{\varepsilon_1k_2}.
$$

\hspace{1cm} \text{(2.34)}

The frequency equations \eqref{eq:2.32} and \eqref{eq:2.33} can also be rewritten in the exponential form

$$
1 + r_{12}e^{2iak_2} = 0 \quad (L_a = 0),
$$

\hspace{1cm} \text{(2.35)}

$$
1 - r_{12}e^{2iak_2} = 0 \quad (L_s = 0).
$$

\hspace{1cm} \text{(2.36)}

Multiplying together these two equations we arrive at the exponential form for the total frequency equation \eqref{eq:2.34}

$$
D(\omega) \equiv 1 - r_{12}^2e^{4iak_2} = 0 \quad (L_aL_s = 0),
$$

\hspace{1cm} \text{(2.37)}

where the notation

$$
r_{12} \equiv \frac{\varepsilon_2k_1 - \varepsilon_1k_2}{\varepsilon_2k_1 + \varepsilon_1k_2} = \frac{\gamma - 1}{\gamma + 1}
$$

\hspace{1cm} \text{(2.38)}

is introduced. It will be shown later (see Eq. \eqref{eq:2.50}), that $r_{12}$ is the reflection amplitude for a single interface.

The frequency equations for the TE-polarization is obtained from the above equations by replacement $\varepsilon_\alpha \rightarrow \mu_\alpha, \quad \alpha = 1, 2$.

To comprehend the structure of the discrete spectrum in the presence of two interfaces we address typical examples. The solutions to the frequency equations \eqref{eq:2.32} and \eqref{eq:2.33} are studied in detail in the theory of dielectric waveguides \cite{46} and optical waveguides \cite{48, 49}, in the theory of surface plasmons \cite{42, 44, 50, 52} and so on. However, in these applications the roots of the frequency equations are often sought of in the form $k = k(\omega)$ (wave vector as function of frequency). We are interested in the inverse function $\omega = \omega(k)$. 

13
While studying the frequency equations (2.32) and (2.33), their plots in terms of the variables \( k_1 \) and \( k_2 \) instead of the initial variables \( k \) and \( \omega \) are helpful and transparent. To this end, the considered frequency equation is appended with the relation between \( k_1^2 \) and \( k_2^2 \) following from their definition (2.23). At fixed \( \omega \) one obtains two equations connecting \( k_1 \) and \( k_2 \). The intersection points of the curves defined by the left-hand sides of these equations give the solutions of the initial frequency equation (see, for example, [46, 53]).

Let us briefly describe the structure of the discrete spectrum of electromagnetic excitations for some configurations. Not all these examples can have a direct relation to the experimental studies of the Casimir forces. Nevertheless, all of them turn out to be instructive in revealing the general properties of the electromagnetic spectrum for two plane parallel interfaces.

We specify the configuration I in the following way:

\[
\varepsilon_1 = \mu_1 = 1, \quad \varepsilon_2 \text{ and } \mu_2 \text{ are some constants} \tag{2.39}
\]

(a material plate in vacuum without dispersion). This configuration is studied in detail in radio engineering as the simplest example of a waveguide [37, 46]. When the conditions

\[
\varepsilon_2 > 0, \quad \mu_2 > 0, \quad \varepsilon_2\mu_2 > 1 \tag{2.40}
\]

or

\[
\varepsilon_2 < 0, \quad \mu_2 < 0, \quad \varepsilon_2\mu_2 > 1 \tag{2.41}
\]

are satisfied, there exist waveguide solutions in the form (2.31) with \( k_1^2 < 0 \) and \( k_2^2 > 0 \) for both the TE- and TM-polarizations. For a given value of \( k^2 \), the number of such solutions is finite and is increasing with \( \omega \). The respective real eigenfrequencies lie in the interval \((c_2k, c_1k)\) with \( c_1 = c \).

As expected, the surface modes \((k_1^2 < 0, k_2^2 < 0)\) in the present configuration exist only under the conditions (2.41), in other words, if the plate is made of the left-handed material (both \( \varepsilon_2 \) and \( \mu_2 \) are negative [54, 55]). In the general case, the number of modes of this kind is equal to 4: there are 2 surface modes with the TE-polarization (symmetric oscillation and antisymmetric oscillation) and 2 analogous modes with the TM-polarization.

For symmetric surface modes it is enough to fulfil the condition (2.41). For antisymmetric
surface modes, one has to impose, in addition to (2.41), the following conditions

\[
0 < \frac{a_\omega}{c} (\varepsilon_2 \mu_2 - 1) < \begin{cases} \\
|\varepsilon_2|^{-1} & \text{TM-polarization;} \\
|\mu_2|^{-1} & \text{TE-polarization.}
\end{cases}
\]

The real frequencies of the surface modes lie in the interval \((0, c_2 k)\).

As the next example we consider configuration II which is complimentary to the previous one, namely, \(\varepsilon_1\) and \(\mu_1\) are some positive or negative constants such that \(\varepsilon_1 \mu_1 > 1\) and \(\varepsilon_2 = \mu_2 = 1\) (two semi-spaces of the same material without dispersion separated by the vacuum gap).

This configuration is not investigated in radio engineering and waveguide optics but it is closely related to the Casimir calculations. In the case of left-handed material, obeying the conditions

\[
\varepsilon_1 < 0, \quad \mu_1 < 0, \quad \varepsilon_1 \mu_1 > 1,
\]

there exist surface symmetric and antisymmetric waves in both polarizations \[ 55, 56 \]. Indeed, one of the branches of the hyperbola defined by the equation

\[
a^2 \kappa_2^2 - a^2 \kappa_1^2 = \frac{a^2 \omega^2}{c^2} (\varepsilon_1 \mu_1 - 1) > 0, \quad k_\alpha = i \kappa_\alpha, \quad \alpha = 1, 2
\]

at negative \(\varepsilon_1\) and \(\mu_1\) always crosses in the first quadrant the curves defined by the equations

\[
ak_1 = -\frac{\varepsilon_1}{\varepsilon_2} (a \kappa_2) \tanh(a \kappa_2), \quad ak_1 = -\frac{\varepsilon_1}{\varepsilon_2} (a \kappa_2) \coth(a \kappa_2)
\]

and two more obtained by replacing \(\varepsilon_\alpha\) by \(\mu_\alpha\), \(\alpha = 1, 2\). Therefore, the discrete spectrum for the present configuration exists only in the case of left-handed materials and consists of 4 surface modes. The frequencies of these modes belong to the interval \(0 < \omega < c_1 k\).

Keeping in mind the possibility of total reflection at the interface of the media 1 and 2 one can try to find the solutions for this configuration with \(k_1^2 > 0\) and \(k_2^2 < 0\). However it is easy to see that there are no such solutions with real frequencies as the equations are complex. Even if such solutions existed, they are not eigenfunctions of the discrete spectrum because they are not squared integrable on the infinite axis \(z\).

For the configuration under consideration there are no waveguide solutions to the Maxwell equations. Indeed, for the existence of such solutions it is required that \(k_1^2 < 0\), and \(k_2^2 > 0\). From these conditions we arrive at the conflicting inequalities \(0 < \omega < c_1 k\) and \(\omega > ck\), with \(c_1 = c/\sqrt{\varepsilon_1 \mu_1} < c\).
Now let us consider the examples of the discrete electromagnetic spectrum explicitly allowing for the temporal dispersion in the media. As configuration III we take a material (metal) slab in vacuum, the dielectric properties of the slab being described by the simple plasma model \( \varepsilon_1 = \mu_1 = 1 \), \( \varepsilon_2(\omega) = 1 - \frac{\omega_p^2}{\omega^2} \), \( \mu_2 = 1 \).

\[
\varepsilon_1 = \mu_1 = 1, \quad \varepsilon_2(\omega) = 1 - \frac{\omega_p^2}{\omega^2}, \quad \mu_2 = 1. \tag{2.45}
\]

This configuration supports two surface waves in the TM polarization. These modes are well studied theoretically \([45, 55]\) and experimentally, for instance, in measurements of the energy losses by the electrons passing through the metal films \([43, 44]\). There is a vast literature on this subject \([42, 50, 52]\). Our citing is minimal.

The physical picture of these collective excitations is the following. At both boundaries of the metal plate \( (z = \pm a) \) with \( a \to \infty \) there exist plasma oscillations of the electron density with the same frequency \( \omega_p/\sqrt{2} \) and dispersion law \( \omega(2.29) \). If the thickness of the plate or film is finite these oscillations interact reciprocally and the energy level \( \omega(2.29) \) splits, as usual, in two levels (asymmetric and symmetric ones) with frequencies \( \omega_a(k) \) and \( \omega_s(k) \) defined by Eqs. \( (2.32) \) and \( (2.33) \), respectively (see Fig. 1b).

It is important that both curves \( \omega_s(k) \) and \( \omega_a(k) \) are placed to the right of the line \( \omega = ck \) and below the horizontal line \( \omega = \omega_p \). Thus the eigenfrequencies of the surface modes lie in the interval \( 0 \leq \omega_s(k), \omega_a(k) < ck \) for \( 0 < k < \infty \).

The curve \( \omega_a(k) \) at all \( k \) lies above the curve \( \omega_s(k) \). Near the origin both the curves touch the line \( \omega = ck \) from the right. With \( k \to \infty \) the curves \( \omega_s(k) \) and \( \omega_a(k) \) tend to the horizontal line \( \omega = \omega_p/\sqrt{2} \), respectively, from below and from above. For \( 2a \to \infty \) the frequencies \( \omega_s(k) \) and \( \omega_a(k) \) tend to the universal curve \( \omega(2.29) \) from below and from above.

The characteristic value of the longitudinal wave vector \( k \) in the problem under consideration is \( k_p = \omega_p/c \). It is within the vicinity of \( k \sim k_p \) where the “bend” of the curves \( \omega_s(k) \) and \( \omega_a(k) \) is observed.

It is evident that there are no waveguide solutions \( (k_1^2 < 0, \ k_2^2 > 0) \) in the present case. Indeed, from the definition of the wave vectors \( k_1 \) and \( k_2 \) (see Eqs. \( (2.28) \) and \( (2.2) \)) we obtain

\[
-k_1^2 + k_2^2 = -\frac{\omega_p^2}{c^2}.
\]

For the waveguide solutions the left-hand side of this equation should be positive. Hence, this equality cannot be satisfied.
FIG. 1: (color online) Dispersion curves for the discrete modes in the TM-polarization for different configurations: single metal–vacuum interface (a); metal plate of thickness $L = 2ak_p = 0.63$ in vacuum (b); vacuum gap of the same width $L = 0.63$ in the metal bulk (c); vacuum gap of the width $L = 6.3$ in the metal bulk (d). Frequencies $\Omega$, $\omega$, and the wave number $q$ are presented in the dimensionless units defined in Eq. (2.28). The gray filled regions correspond to the continuous spectrum.

Now we consider configuration IV, complimentary to the previous one, namely, a vacuum slot, $2a$ in width, in the bulk metal described by the plasma model (see Fig. 1c,d)

$$
\varepsilon_1 = 1 - \frac{\omega_p^2}{\omega^2}, \quad \mu_1 = 1, \quad \varepsilon_2 = \mu_2 = 1.
$$

First, we consider the surface waves in the present set-up, $k_1^2 < 0$, $k_2^2 < 0$, which exist in the TM polarization \[45\]. Again, we have two such collective modes, symmetric and antisymmetric ones, their frequencies being placed in the interval $(0, ck)$. The lay-out of the dispersion curves is interchanged in comparison with the previous case, $\omega_s(q) > \omega_a(q)$. The
curve $\omega_a(q)$ lies below the horizontal line $\omega = 1/\sqrt{2}$ and to the right from the line $\omega = q$. At the point $q = q_{cr} = 1/\sqrt{1 + L/2}$ the dispersion curve $\omega_s(k)$ crosses the light line $\omega = q$ and becomes the lowest waveguide mode (see Fig. 1c,d) and \[43\]. Thus the symmetric surface mode $\omega_s(q)$ becomes in this configuration a ‘hybrid’ one. It is this fact that leads to the known result, namely, the contribution of the surface modes to the Casimir energy for a given configuration proves to be considerable only at small distances. Indeed, because of the hybrid nature of the symmetric mode, the dispersion curves $\omega_s(q)$ and $\omega_a(q)$ move apart in the region $q < q_{cr}$ (Fig. 1c,d), this divergence being maximum at small $L$ (compare Fig. 1c and Fig. 1d). Obviously this implies in turn that the mutual interaction of these collective excitations is maximum at small $L$.

With increasing the gap width $L$, in this configuration there appear waveguide solutions ($k_1^2 < 0$, $k_2^2 > 0$) satisfying the conditions

$$c^2 k^2 < \omega_{wg}^2(k) < \omega_p^2 + c^2 k^2.$$ \hspace{1cm} (2.47)

Thus, they lie to the left from the line $\omega = ck$ and below the curve $\omega = \sqrt{\omega_p^2 + c^2 k^2}$. Approximately the frequency of these modes and their total numbers, for each polarization, are given by \[32\]

$$\omega^2(k) \approx k^2 c^2 + n^2 \pi^2 c^2 / 4a^2, \quad n = 0, 1, 2, \ldots, n < 2a\omega_p / \pi c.$$ \hspace{1cm} (2.48)

These modes exist only at large gaps (compare Fig. 1c and 1d). Indeed, for gold $\omega_p = 1.38 \cdot 10^{16}$ s$^{-1}$. Therefore, the dimensionless width of the gap $L = 0.63$ implies $2a = 14$ nm and $L = 6.3$ corresponds to $2a = 140$ nm. In the first case, there are no pure waveguide modes (Fig. 1c) and, at the same time, the surface modes interact strongly because their dispersion curves are distinguished considerably. In the second case (Fig. 1d), only two pure waveguide modes appear while the surface modes at $q > 1$ practically coincide with each other and with the single interface dispersion curve $\Omega(q)$. The latter means that in this region the surface modes do not couple. For copper, we have close figures: $\omega_p = 1.46 \cdot 10^{16}$ s$^{-1}$, $2a = 12.6$ nm ($L = 0.63$), and $2a = 126$ nm ($L = 6.3$).

The fact that waveguide modes exist only for large gaps suggests that they contribute appreciably to the dispersion force at large distances \[32\], where contributions of the surface

\[5\] Probably, this implies that the symmetric surface TM-mode in this configuration may directly be excited by the light beam contrary to the plate configuration, Fig. 1b \[42-44, 50\].
modes practically vanish.

The examples studied above reveal general properties of the discrete spectrum in the problem at hand and permit us to establish the lower boundary of the continuous spectrum. Let us summarize these properties:

i) The discrete spectrum may comprise the solutions of two types: the surface modes and the wave guide modes;

ii) At fixed \( k \) the frequencies of the surface modes (if they exist) lie in the interval \((0, \omega_-(k))\), while the frequencies of the waveguide solutions (if they exist) belong to the interval \((\omega_-(k), \omega_+(k))\), where the boundary values \( \omega_-(k) \) and \( \omega_+(k) \) \((\omega_-(k) < \omega_+(k))\) are defined by the explicit form of the dielectric function \( \varepsilon(\omega) \);

iii) The lower boundary of the continuous spectrum is defined by the condition \( k_1^2(\omega) > 0 \).

Here we list the values of \( \omega_+(k) \) and \( \omega_-(k) \) for the configurations I – IV.

I: \( \omega_-(k) = c_2 k \equiv \frac{ck}{\sqrt{\varepsilon_2 \mu_2}} \), \( \omega_+(k) = ck \), \( c_2 < c \).

In this case the discrete spectrum may include the surface modes and the waveguide modes with the frequencies from the above specified intervals; the continuous spectrum \( \omega \) is defined by \( \omega > \omega_+(k) \).

II: \( \omega_-(k) = c_1 k \equiv \frac{ck}{\sqrt{\varepsilon_1 \mu_1}} \), \( \omega_+(k) = ck \), \( c_1 < c \).

The discrete spectrum may consist of the surface modes only with the frequencies from the above specified interval; the continuous spectrum \( \omega \) exists for \( \omega > \omega_-(k) = c_1 k \).

III: \( \omega_-(k) = ck \), \( \omega_+(k) = \sqrt{c^2 k^2 + \omega_p^2} \).

The discrete spectrum is formed by the surface modes with frequencies from the interval specified above; the continuous spectrum is defined by \( \omega > \omega_-(k) = ck \).

IV: \( \omega_-(k) = ck \), \( \omega_+(k) = \sqrt{c^2 k^2 + \omega_p^2} \).

The discrete spectrum comprises the surface modes and the waveguide modes with frequencies in the corresponding intervals; the continuous spectrum exists for \( \omega > \omega_+(k) = \sqrt{c^2 k^2 + \omega_p^2} \).
In what follows it is significant that the points $\omega_-(k)$ and $\omega_+(k)$ are the branch points for the root functions $k_1(\omega)$ and $k_2(\omega)$ (see Sec. IIIA).

The configurations considered above are unbounded, i.e. open. As a result in addition to the real roots the frequency equations have also discrete complex roots $\omega(k) = \omega'(k) + i\omega''(k)$ which correspond to the quasi-normal modes [31]. These modes are not squared integrable and, therefore, they are not normalizable. That is why the quasi-normal modes are not included into the completeness relation. However their existence should be taken into account when choosing the contours for integration in the complex $\omega$ plane (see Sec. IIIA).

It is worth noting here that the quasi-normal modes are explored in fact in the experiments dealing with the radiating plasmons [44]. Usually, in this field the complex wavenumbers are considered $k(\omega) = k'(\omega) + ik''(\omega)$ instead of the complex eigenfrequencies.

2. Treatment of the continuous part of the spectrum

To study the contribution of the continuous spectrum to the vacuum energy, the scattering matrix is required, i.e. the $S$-matrix for the wave equations (2.17) and (2.18) with the matching conditions (2.19) and (2.20), respectively. Here we deal with one-dimensional scattering on the infinite $z$-axis, $-\infty < z < \infty$. This problem has some peculiarities [57–60]. Specifically, one has to consider the incidence of the initial waves from the left and from the right separately. Thus, we must add such initial waves to the outgoing and standing waves in Eqs. (2.22) and (2.31) considered in the pertinent eigenvalue problems. The respective reflection amplitudes, $r_l$, $r_r$, and transition amplitudes, $t_l$, $t_r$, make up a $(2 \times 2)$ matrix that plays the role of the scattering matrix in the problem under consideration

$$S(\omega) = \begin{pmatrix} t_l & r_l \\ r_r & t_r \end{pmatrix}. \quad (2.49)$$

a. Single plane interface In the case of the one plane interface ($\varepsilon_1, \mu_1 \mid \varepsilon_2, \mu_2$) we have for the TM-polarization

$$r_l \equiv r_{12} = \frac{\varepsilon_2 k_1 - \varepsilon_1 k_2}{\varepsilon_1 k_2 + \varepsilon_2 k_1}, \quad r_r \equiv r_{21} = -r_{12} = -r_l, \quad (2.50)$$

$$t_l \equiv t_{12} = \frac{2\varepsilon_1 k_1}{\varepsilon_1 k_2 + \varepsilon_2 k_1}, \quad t_r \equiv t_{21} = \frac{2\varepsilon_2 k_2}{\varepsilon_1 k_2 + \varepsilon_2 k_1}, \quad t_{12} \neq t_{21}. \quad (2.51)$$
The analogous amplitudes for the TE-polarization are obtained from Eqs. (2.50) and (2.51) by the substitution $\varepsilon_\alpha \rightarrow \mu_\alpha$, $\alpha = 1, 2$.

The amplitudes $t$ and $r$ for the TM- and TE-polarizations have the poles at the points where the variable $\omega$ coincides with the eigenfrequencies defined by Eqs. (2.25) and (2.26). This property is preserved for several interfaces too (see below). The single plane interface is non symmetric configuration, therefore the $S$-matrix (2.49) in this case does not possess appealing physical properties.

b. Electromagnetic scattering by two parallel plane interfaces

Now we address the scattering matrix for two plane interfaces which are parallel to the $xy$ plane and cut the $z$ axis at the points $z = -a$ and $z = a$, in other words, we envisage the configuration $(\varepsilon_1, \mu_1 \mid \varepsilon_2, \mu_2 \mid \varepsilon_3, \mu_3)$. The explicit form of $t$ and $r$ is again derived from the matching conditions (2.19) and (2.20) [35, 36]. Taking careful account of the phase factors at the points $z = -a$ and $z = a$ one obtains

$$ r_l \equiv r_{123} = \frac{r_{12} + r_{23}e^{4ik_2a}}{1 + r_{12}r_{23}e^{4ik_2a}}, \quad t_l \equiv t_{123} = \frac{t_{12}t_{23}e^{2ik_2a}}{1 + r_{12}r_{23}e^{4ik_2a}}, \quad (2.52) $$

$$ r_r \equiv r_{321} = \frac{r_{32} + r_{21}e^{4ik_2a}}{1 + r_{32}r_{21}e^{4ik_2a}}, \quad t_r \equiv t_{321} = \frac{t_{32}t_{21}e^{2ik_2a}}{1 + r_{32}r_{21}e^{4ik_2a}}, \quad (2.53) $$

where $r_{ij}$ and $t_{ik}$ are defined in Eqs. (2.50) and (2.51).

Further we consider the special case of (2.52) and (2.53), the symmetric one, $(\varepsilon_1, \mu_1 \mid \varepsilon_2, \mu_2 \mid \varepsilon_1, \mu_1)$. In the symmetric set-up one has

$$ r = r_l = r_r \equiv r_{121} = \frac{r_{12} - r_{12}e^{4ik_2a}}{1 - r_{12}^2e^{4ik_2a}}, \quad t = t_l = t_r \equiv t_{121} = \frac{t_{12}t_{21}e^{2ik_2a}}{1 - r_{12}^2e^{4ik_2a}}. \quad (2.54) $$

The amplitudes $r$ and $t$ in Eq. (2.54) have the poles at the points of the discrete spectrum (see Eq. (2.37)), and they obey the relations

$$ |t|^2 + |r|^2 = 1, \quad (2.55) $$

$$ rt + \bar{r}t = 0, \quad (2.56) $$

where the bar means complex conjugation. Now the scattering matrix (2.49) is given by

$$ S(\omega) = \begin{pmatrix} t & r \\ r & t \end{pmatrix}. \quad (2.57) $$

Due to Eqs. (2.55) and (2.56) the $S$-matrix (2.57) is a symmetric unitary matrix

$$ SS^\dagger = S^\dagger S = 1. \quad (2.58) $$
In the case of potential scattering on an infinite line with the symmetric potential the amplitudes \( t \) and \( r \) are parametrized as follows [59]:

\[
t = \cos \theta e^{i \delta}, \quad r = i \sin \theta e^{i \delta},
\]

(2.59)

where \( \theta \) and \( \delta \) are the real functions of \( \omega \). Further we have

\[
\det S(\omega) = t^2(\omega) - r^2(\omega) = e^{2i\delta(\omega)} = \frac{t(\omega)}{t(\omega)},
\]

(2.60a)

(2.60b)

For the real \( \omega \) the function \( \det S(\omega) \) is defined by formula (2.60a), while (2.60b) gives its continuation to the whole complex plane \( \omega \).

In order to consider in this approach the initial asymmetric configuration \( (1|2|3) \), one has to proceed from the symmetric multilayered configuration \( (1|2|3|2|1) \), calculate the respective total reflection and transition amplitudes, and find \( \det S(\omega) \). Transition to the initial asymmetric configuration should be done only at the final stage of the vacuum energy calculation (see Sec. IIIA) by moving the interface 3|2 to infinity.

III. CASIMIR ENERGY

We define the Casimir energy as the renormalized zero point energy of the electromagnetic oscillations for configuration at hand

\[
E = \frac{\hbar}{2} \sum_{\{q\}} \omega_q.
\]

(3.1)

Here the sum sign implies the summation over the discrete part of the spectrum and the integration over its continuous branch.

The summing up of the discrete eigenfrequencies will be performed by making use of the frequency equations. The integration over the continuous part of the spectrum cannot be carried out by applying the ‘naive’ formula

\[
\int \omega \, d\omega,
\]

(3.2)

because it does not ‘feel’ the physical nature of the problem under consideration, namely, this integral does not depend on the specific form of the differential operator and the corresponding boundary conditions [31]. Therefore, the summation over the continuous branch of
the spectrum should be accomplished, as usual, by making use of the spectral density shift.

The rigorous mathematical theory of the scattering problem gives the following expression for this function \[ \Delta \rho(\omega) \equiv \rho(\omega) - \rho_0(\omega) = \frac{1}{\pi} \frac{d}{d\omega} \delta(\omega) \]

\[ = \frac{1}{2\pi i} \frac{d}{d\omega} \ln \det S(\omega) = \frac{1}{2\pi i} \frac{d}{d\omega} \ln \frac{t(\omega)}{\bar{t}(\omega)}. \]

where \( S(\omega) \) is the \( S \)-matrix in the spectral problem at hand. In Eqs. (3.3) \( \rho(\omega) \) is the density of states for a given potential (or for given matching conditions in the case of the compound media) and \( \rho_0(\omega) \) is the spectral density in the respective free spectral problem (for the vanishing potential or for the homogeneous unbounded space). In the case of the one-dimensional scattering the calculation of the spectral density was considered in [59, 62].

It is worth noting here that already at the level of the spectral density (3.3) the removing of infinity is carried out, namely, the contribution to the vacuum energy generated by the unbounded Minkowski space is subtracted here.

Taking into account all this we can work out Eq. (3.1) in detail as follows:

\[ E(2a) = \frac{\hbar}{2} \sum_\sigma \int_{-\infty}^{\infty} \frac{d^2k}{(2\pi)^2} \left[ \sum_n \omega_n(\sigma, k, a) + \int_{\omega_0}^{\infty} \omega \Delta \rho(\sigma, \omega, k, a) d\omega \right] - (a \to \infty). \]

Here \( k \) is the wave vector along unbounded dimensions \( k = (k_x, k_y) \); \( \omega_n(\sigma, k, a) \) are the frequencies appertaining to the discrete spectrum; the function of the spectral density shift \( \Delta \rho(\omega) \) is given by Eqs. (3.3); \( \omega_0 \) is the lower bound of the continuous spectrum. Summation over \( \sigma = \text{TE}, \text{TM} \) in (3.4) takes into account two polarizations of the electromagnetic field.

The further treatment of Eq. (3.4) is aimed at deriving a unique integral representation for the contributions of both the discrete part and the continuous part of the spectrum, the integration being carried out over the imaginary frequencies \( \omega = i\zeta \).

To be definite, we shall consider the most ‘richest’ electromagnetic spectrum possessing the surface modes, waveguide modes, and the continuous part (see, for example, the configurations I and IV in Sec. II B 1). As was shown there, the frequencies of the surface modes lie in the interval \( 0 < \omega_{sm} < \omega_-(k) \), the frequencies of the waveguide modes belong to the band \( \omega_-(k) < \omega_{sm} < \omega_+(k) \), and for the frequencies \( \omega \) of the continuous part of the spectrum we have \( \omega_+(k) < \omega \) (see Fig. 2).
A. Transition to imaginary frequencies

In what follows, we have to go out in the complex frequency plane \( \omega \). For this the one-valued branches of the integrand in Eq. (3.4) should be chosen. The square root dependence

\[
    k_\alpha(\omega) = \sqrt{\varepsilon_\alpha(\omega) \frac{\omega^2}{c^2} - k^2}, \quad \alpha = 1, 2
\]

results in branch points. For the usually accepted functions \( \varepsilon(\omega) \) there appear four such points on real axes: \( \pm \omega_-(k) \) and \( \pm \omega_+(k) \) \((0 \leq \omega_-(k) < \omega_+(k))\) (see Sec. II B 1). These are the same points that separate the different parts of the spectrum.

We draw two cuts on the real axes \( \omega \): the first cut connects the points \( -\omega_- \) and \( \omega_- \) and the second one starts at the point \( \omega_+ \) and goes to infinity (see Fig. 2). The first cut passes round the eigenfrequency of the surface mode \( \omega_{sm} \) from below. It is not crucial and this cut can go round \( \omega_{sm} \) from above as well. Further, we assume that \( k_1(\omega) \) and \( k_2(\omega) \) in Eq. (3.5) acquire real positive values at the upper edges of the cuts.

The eigenfrequencies \( \omega_n(\sigma, k, a) \) are unknown in an explicit form, we have only the respective frequency equations (2.32) and (2.33) or in another form (2.35) – (2.37). This dictates, without choice, the making use of the argument principle theorem from the complex analysis when summing over \( n \) in (3.4). When choosing a contour for integration in the complex \( \omega \) plane one should bear in mind that the left-hand sides of the frequency equations \( D(\sigma, \omega) \)
considered as the functions of the complex variable $\omega$ have a ‘good’ behaviour in the upper half-plane $\omega$ only

$$D(\sigma, \omega) = 1 - r^2 e^{iak_2}, \quad ck_2 = \sqrt{\omega^2 - \omega^2}. \quad (3.6)$$

This forbids from the very beginning the deformation of the contour in such a way that it includes the whole imaginary axes $\text{Im}\,\omega$. An admissible contour is obviously the following one: the integration should be performed along the circles $C_\epsilon$ of the radius $\epsilon$ with $\epsilon \to 0$, each circle surrounding a single root of the frequency equation (see Fig. 2).

When treating the contribution of the continuous part of the spectrum to the vacuum energy one should keep in mind the following. Upon substituting (3.3b) in $\Delta \rho(\omega)$ the transition amplitude from (2.54)

$$t(\omega) = t_{12} t_{21} e^{2iak_2} D(\omega), \quad (3.7)$$

in vacuum energy (3.4) there appear terms which are proportional to the distance between the slabs $2a$. These contributions are generated by the factor $e^{2iak_2}$ and they belong to the internal energy of the medium $2$ in the configuration under consideration. These terms are removed from the Casimir energy by the subtraction indicated in Eq. (3.4). Hence, in calculation of the vacuum electromagnetic energy the denominator $D(\omega)$ in Eq. (3.7) ‘works’ alone.

Now the vacuum energy (3.4) acquires the form

$$E(2a) = \frac{\hbar}{2} \sum_\sigma \int_0^\infty \frac{dk}{2\pi} \frac{1}{2\pi i} \left[ \int_{C_\epsilon} d\omega \omega \frac{d}{d\omega} \ln D(\sigma, \omega) + \int_{\omega_+}^\infty d\omega \omega \frac{d}{d\omega} \ln \frac{D(\sigma, \omega)}{D(\sigma, \omega)} \right]. \quad (3.8)$$

Further, we represent the contribution of the continuous spectrum to the vacuum energy (the second term between the square brackets in Eq. (3.8)) in the form of the contour integrals as well. According to the Cauchy integral theorem, we can write

$$\int_{C_+} d\omega \omega \frac{d}{d\omega} \ln D(\sigma, \omega) = 0, \quad (3.9a)$$

$$\int_{C_-} d\omega \omega \frac{d}{d\omega} \ln \bar{D}(\sigma, \omega) = 0, \quad (3.9b)$$

where the contours $C_+$ and $C_-$ are shown in Fig. 2. Here we have taken into account that the complex roots of the equation $D(\sigma, \omega) = 0$ lie only in the lower half-plane $\omega$ and, respectively, the complex roots of the equation $\bar{D}(\sigma, \omega) = 0$ are placed only in the upper
half-plane $\omega$. Such a lay-out of the complex eigenfrequencies is in a direct relation with the choice of the time dependence in the solutions to the Maxwell equations in the form $e^{-\omega t}$ (see Sec. ). In view of relations (3.9), we can express the contribution of the continuous part of the spectrum in (3.8) as the integrals along the contours $C_+$ and $C_-$ which have no section $(\omega_+, \infty)$. One can easily see from Fig. 2 that along the contours $C_\varepsilon$ the contributions of the discrete spectrum and continuous spectrum are mutually canceled. Besides, at the length $(0, \omega_+)$ the contributions of the continuous part of the spectrum generated by $D(\sigma, \omega)$ and $\bar{D}(\sigma, \omega)$ are mutually canceled too.

As a result, we arrive at a very compact and clear formula for the Casimir energy

$$E(2a) = \frac{\hbar}{2\pi} \sum_{\sigma} \int_{0}^{\infty} \frac{k dk}{2\pi} \int_{0}^{\infty} d\zeta \ln D(\sigma, i\zeta, k), \quad \sigma = TE, TM, \quad (3.10)$$

where

$$D(\sigma, i\zeta, k) = 1 - r_{\sigma}^2(i\zeta, k) e^{4a\kappa_2(\zeta, k)}, \quad \sigma = TE, TM,$$

$$r_{TE}(i\zeta, k) = \frac{\kappa_1(\zeta, k) - \kappa_2(\zeta, k)}{\kappa_1(\zeta, k) + \kappa_2(\zeta, k)}, \quad r_{TM}(i\zeta, k) = \frac{\varepsilon_2(i\zeta)\kappa_1(\zeta, k) - \varepsilon_1(i\zeta)\kappa_2(\zeta, k)}{\varepsilon_2(i\zeta)\kappa_1(\zeta, k) + \varepsilon_1(i\zeta)\kappa_2(\zeta, k)}, \quad (3.11)$$

$$\kappa_\alpha(\zeta, k) \equiv ik_\alpha(i\zeta, k) = \sqrt{\varepsilon_\alpha(i\zeta)^2 + k^2}, \quad \alpha = 1, 2.$$  

In obtaining formula (3.10) the integration by parts was carried out with respect to the variable $\zeta$: $\omega = i\zeta$. Obviously, this formula holds for an arbitrary spectrum of electromagnetic excitations sustained by the configuration under consideration. Let us remind that the symmetric configuration is considered with nonmagnetic materials $(\varepsilon_1(\omega), \mu_1 = 1|\varepsilon_2(\omega), \mu_2 = 1|\varepsilon_1(\omega), \mu_1 = 1)$.

Differentiation of the vacuum energy (3.10) with respect to the gap width $2a$ gives immediately the Lifshitz formula for the Casimir force at zero temperature

$$F(2a) = -\frac{\partial E(2a)}{\partial(2a)} = -\frac{\hbar}{2\pi^2} \int_{0}^{\infty} k dk \int_{0}^{\infty} d\zeta \kappa_2(\zeta, k) \sum_{\sigma} [r_{\sigma}^{-2}(i\zeta, k) e^{4a\kappa_2(\zeta, k)} - 1]^{-1}. \quad (3.12)$$

Here $\sigma = TE, TM$ as before and the same notation (3.11) is used.

---

6 A simple example of the complex frequencies in solutions to the Maxwell equations for an open system (a perfectly conducting sphere in vacuum) was discussed in Ref. [31].

7 In earlier papers dealing with other configurations the analogous cancellation was brought out by making use of the complex $k_2$-plane (see, for example, [63, 64]). However the Lifshitz formula is presented in terms of the variable $i\zeta = \omega$. 
In order to reproduce exactly the Lifshitz formula (2.9) in [7] for a vacuum gap \((\varepsilon_2 = \mu_2 = 1)\) between the identical slabs a new variable \(p = p(k)\) should be introduced

\[
\frac{p\zeta}{c} \equiv \kappa_2 = \left(\frac{\zeta^2}{c^2} + k^2\right)^{1/2}.
\]  

(3.13)

Taking into account that \(p(k = 0) = 1\) and

\[
\kappa_2 k \, dk = \frac{p^2\zeta^3}{c^3} \, dp,
\]

we easily convert Eq. (3.12) to the form

\[
F(2a) = -\frac{\hbar^2}{2\pi^2 c^3} \int_0^{\infty} \zeta^3 \, d\zeta \int_1^{\infty} p^2 \, dp \sum_{\sigma} \left[ r_{\sigma}^{-2}(i\zeta, p)e^{4ap\zeta/c} - 1 \right]^{-1},
\]

(3.14)

where

\[
r_{\text{TE}}^{-2}(i\zeta, p) = \left(\frac{\sqrt{\varepsilon_1(i\zeta) - 1 + p^2} + p}{\sqrt{\varepsilon_1(i\zeta) - 1 + p^2} - p}\right)^2, \quad r_{\text{TM}}^{-2}(i\zeta, p) = \left(\frac{\sqrt{\varepsilon_1(i\zeta) - 1 + p^2} + \varepsilon_1(i\zeta)p}{\sqrt{\varepsilon_1(i\zeta) - 1 + p^2} - \varepsilon_1(i\zeta)p}\right)^2.
\]

IV. CONCLUSION

Our derivation of the Lifshitz formula (3.10) is accomplished in the framework of the rigorous spectral summation method. We believe that in this approach the answers are given to many questions in this field which have been waiting for their solutions for a long time. First of all, it is simultaneous incorporation, on the same footing, of the discrete and continuous parts of electromagnetic spectrum, consistent treatment of the branch cuts in the \(\omega\) plane, consideration of the complex eigenfrequency location and so on. The principal novelty of our approach is a special choice of appropriate passes in the contour integrals which are used for transition to imaginary frequencies. For the first time contours of this type were employed in our preceding paper [65] dealing with a close problem. The main idea of our approach is easy-to-grasp. It is sufficient to look attentively at Fig. 2 and the mechanism of mutual cancellations between contributions of the discrete and continuous parts of the spectrum becomes evident as well as the final result, Lifshitz formula (3.10). Without doubt, it is an important advantage of our consideration.

8 By the way, it is these contours that had to be used in our preceding paper [66] considering dielectric cylinder without dispersion.
By making use of the contours $C_+$ and $C_-$ shown in Fig. 2 one can easily ‘explain’ in what way the correct Lifshitz formulae (3.10) and (3.11) may be ‘derived’ by summing up only the discrete eigenfrequencies (1, 3, 4, 10, 18). Let us ignore the branch cuts in the $\omega$ plane, the complex eigenfrequencies (quasi-normal modes), and the bad behavior of the left-hand side of the frequency equation $D(\sigma, \omega)$ in the lower half-plane $\omega$. After that one may ‘glue’ the sections of the contours $C_+$ and $C_-$ which are along the positive Re $\omega$ axis and drop them. As a result, we obtain a unique contour involving the whole Im $\omega$ axis and a semi-circle of a large radius in the right half-plane. Using this contour in the first integral between the square brackets in Eq. (3.8) we arrive immediately at the final Eq. (3.10). Proceeding in an analogous way one may ‘derive’ the Lifshitz formula in the scattering formalism alone (19, 20).

It should be noted here that the comparative analysis of the contributions to the vacuum energy generated by surface, waveguide, and photonic modes has recently been carried out by M. Bordag [67].

In the Lifshitz formula (3.10) written in terms of the integral over imaginary frequencies there are no traces of the electromagnetic spectrum details in the problem at hand; in other words, this formula has the same universal form for all physically admissible material media. Presumably, it implies that the problem of finding the vacuum energy with allowance for the material characteristics of media is, on its nature, a statistical problem. Therefore, an appropriate mathematical method here would be the dissipation-fluctuation theorem formulated, from the very beginning, in terms of imaginary time. One can anticipate that this may simplify the transition to imaginary frequencies in the Lifshitz approach.

Many important topics are left beyond our consideration. One of them is the allowance for the dissipation when calculating the vacuum energy. There are many approaches to this problem (see, for example, [68] and more recent papers [69]) but till now it is unclear how to come to an agreement with rigorous spectral summation method which is based on the real eigenfrequencies in the pertinent spectral problem.

Acknowledgments

Many topics of this paper were discussed with M. Bordag who, in particular, draw our attention to the special class of electromagnetic excitations in media called the wave guide.
waves. We are indebted to him for fruitful collaboration.
