Summary Immunotherapy is one of the major breakthroughs in cancer treatment. However, many patients do not benefit from this type of therapy. Thus, there is an urgent need for a strategy to predict treatment efficacy before start of therapy. The role of certain genetic and epigenetic factors as potential predictive markers for response to immunotherapy is discussed in this short review.

Keywords Epigenetics · Biomarkers · Prediction · Oncology · Immune checkpoint inhibitors

Abbreviations
CGI CpG island
CpG Cytosine-guanine
CTLA4 Cytotoxic T-lymphocyte-associated protein 4
FFPE Formalin-fixed paraffin-embedded
FOXP1 Forkhead box P1
ICI Immune checkpoint inhibition
MMR DNA mismatch repair
MSI Microsatellite instability
NSCLC Non-small cell lung cancer
ORR Overall response rate
OS Overall survival
PD1 Programmed cell death protein 1
PD-L1 Programmed cell death ligand 1
PFS Progression-free survival
SCLC Small cell lung cancer
TMB Tumor mutational burden

Introduction

Inhibition of immune checkpoint molecules—including cytotoxic T-lymphocyte-associated protein 4 (CTLA4), programmed cell death protein 1 (PD-1) and programmed cell death ligand 1 (PD-L1)—has become a promising treatment option for a number of advanced cancers over the past few years [1–6]. However, a significant proportion of patients will not benefit from this type of therapy. Thus, there is huge interest to identify molecular changes which may be used as markers to predict tumor response to immune checkpoint inhibitors (ICI).

Based on the mechanism of PD-1 and PD-L1 interaction, large effort has been taken to investigate the impact of PD-L1 expression on the efficacy of PD-1 inhibition [7]. Davis et al. retrospectively analyzed data from 45 clinical trials of anti-PD-1 or anti-PD-L1 antibodies in 15 tumor entities and reported a predictive value of PD-L1 in 28.9% of these studies (not predictive in 53.3% and not tested in 17.8%) [7]. Thus, although it seems that PD-L1 expression has some impact on the patients’ outcome, it is imperfect as a reliable marker to predict tumor response to ICI, and additional markers or marker combinations are needed.

It is well known that human tumors may harbor a large number of somatic mutations with varying frequencies between tumor entities [8]. Nonsynonymous somatic mutations lead to altered amino acid sequences of proteins and formation of neoantigens. Thus, tumors with higher tumor mutational burden (TMB) carry a larger number of neoantigens which, in theory, increases their immunogenicity and their responsiveness to immunotherapy [9]. Indeed, associations between high TMB and response to ICI were reported in various cancer types including non-small cell lung cancer (NSCLC), small cell lung cancer.
Epigenetic mechanisms including DNA methylation and chemical modifications of histone proteins like methylation, phosphorylation, ubiquitination, acetylation and ADP-ribosylation significantly contribute to the regulation of transcriptional gene activity. These modifications are key events which affect transcription factor binding to DNA and change the chromatin structure resulting either in gene activation or gene silencing [20]. Epigenetic gene regulation is important for the regulation of many biological processes, including embryogenesis, genomic imprinting or X chromosome inactivation [19, 20].

DNA methylation is the covalent addition of a methyl group (–CH3) to the 5′ carbon of cytosine bases within cytosine–guanine (CpG) dinucleotides. In the mammalian genome the CpG dinucleotide is generally underrepresented [21]. However, certain regions of the genome (0.5–4 kb in length) contain CpG dinucleotides at a high density and are called CpG islands (CGI). In humans, these regions are found in approximately 60% of gene promoter regions and less frequently in gene bodies or in intergenic regions [22]. While 70–80% of all non-CGI CpG dinucleotides in the human genome are methylated, cytosines of CpG dinucleotides in CGIs usually remain unmethylated. Exceptions are CGIs associated with imprinted, X-linked and tissue-specific expressed genes [22].

DNA methylation is considered important in the pathogenesis of many solid tumors as well as hematological malignancies [19, 23]. CGIs of various cancer-related genes are frequently methylated in cancer cells, resulting in transcriptional inactivation of these genes [19, 24]. Of note, altered DNA methylation in regions outside CpG islands may be equally important in tumorigenesis, with hypomethylation as relevant as hypermethylation [25].

Several studies revealed that DNA methylation profiling may serve as novel tool in oncology for improved classification and differential diagnosis of carcinomas, especially brain tumors and sarcomas [26, 27]. Moreover, the potential of DNA methylation pattern as prognostic or predictive marker of response to specific therapies including chemotherapy, targeted therapy and immunotherapy in several tumor types was reported previously [28–30].

**DNA methylation as potential biomarker for immunotherapy**

DNA methylation in the human genome can be comprehensively profiled using high-throughput assays based either on microarrays (e.g., Infinium Human-Methylation450 BeadChip, MethylationEPIC BeadChip; Illumina, San Diego, CA, USA) or next-generation sequencing (e.g., reduced representation bisulfite sequencing). MethylationEPIC beadChips are the latest generation of Illumina’s beadarrays and are used to quantitatively analyze methylation of more than 850,000 methylation sites across the genome at single-nucleotide resolution. This approach is not restricted to fresh tissue samples but can also be applied to formalin-fixed paraffin-embedded (FFPE) tissue. In a multicenter study, Duruisseaux et al. [30] used this technology to analyze the methylene of stage IV NSCLC patients who were treated with anti-PD-1-ICI during the course of their disease. In a first step, the authors analyzed tumors from 34 NSCLC patients before they received anti-PD1-ICI. Ten of these patients were classified as responders to this type of therapy and 24 patients were classified as nonresponders. Biostatistical analyses of the microarray data revealed a signature (referred to as EPIMMUNE signature) of 301 differentially methylated CpG sites (81% hypermethylated; 19% hypomethylated; associated with 174 unique genes) between responders and nonresponders. Pathway enrichment analyses revealed that some of these genes are involved in DNA repair, β-catenin signaling and interferon-γ sig-
naline. The EPIMMUNE signature was significantly associated with progression-free survival (PFS) and overall survival (OS) suggesting that EPIMMUNE may be a good predictor of anti-PD-1-ICI response [30]. Neither PD-L1 expression nor TMB were associated with PFS or OS in this patient cohort. In a second step, the authors performed similar experiments in an independent cohort of 47 patients with advanced NSCLC. Again, the EPIMMUNE signature was associated with PFS and OS supporting the predictive potential of this methylation signature [30]. Finally, to increase the usability of their findings in the future clinical routine, the authors identified the best single predictive methylation marker from the EPIMMUNE signature, namely forkhead box P1 (FOXP1). A third cohort of 61 NSCLC patients was tested for FOXP1 methylation using pyrosequencing and hypomethylation of this gene was found to be an independent predictor of PFS and OS in a multivariable model [30].

A similar approach to identify a set of CpG sites predictive for response to anti-PD-1/PD-L1 therapy in advanced NSCLC patients was published by Kim et al. [31]. In this study, tumor samples of 60 NSCLC patients were analyzed using MethylationEPIC beadChips and 377 differentially methylated CpG sites between responders and nonresponders were identified. The vast majority of these CpG sites were hypomethylated in nonresponders [31]. Based on these data, the authors calculated a predictive methylation model consisting of 8 genes (IRF6, CTSD, GRN, LTB, TRIM36, EVL, CD3E and LCP1). Unfortunately, the authors did not provide information about the predictive value of FOXP1 methylation in their patient cohort. Noteworthy, the clinical benefit in this cohort was not associated with TMB, neo-antigen load, aneuploidy level or PD-L1 expression [31].

An example of a single DNA methylation event as potential predictive marker for immunotherapies was reported by Goltz et al. in melanoma patients [32]. The authors analyzed methylation of the CTLA4 promoter in a set of 50 anti-PD-1/CTLA-4-ICI treated patients with metastasized malignant melanoma by methylation-specific quantitative real-time PCR. Low CTLA4 methylation was significantly correlated with response to therapy and OS [32].

In summary, the above mentioned studies suggest that DNA methylation pattern may be of predictive relevance for response to immunotherapies in the future; however, available data are still very limited and a multitude of additional studies are needed to strengthen this concept.

**Take home message**

Treatment with ICI can generate durable responses in a subset of cancer patients. Promising data about TMB, MSI and DNA methylation as future markers to predict response to ICI are available.
