ABSTRACT

Context. The high-mass microquasar Cyg X-1, the best-established candidate for a stellar-mass black hole in the Galaxy, has been detected in a flaring state at very high energies (VHE), E > 200 GeV, by the Atmospheric Cherenkov Telescope MAGIC. The flare occurred at orbital phase φ = 0.91, where φ = 1 is the configuration with the black hole behind the companion high-mass star, when the absorption of gamma-ray photons by photon-photon annihilation with the stellar field is expected to be highest.

Aims. We aim to set up a model for the high-energy emission and absorption in Cyg X-1 that can explain the nature of the observed gamma-ray flare.

Methods. We study the gamma-ray opacity due to pair creation along the whole orbit, and for different locations of the emitter. Then we consider a possible mechanism for the production of the VHE emission.

Results. We present detailed calculations of the gamma-ray opacity and infer from these calculations the distance from the black hole where the emitting region was located. We suggest that the flare was the result of a jet-clump interaction where the decay products of inelastic p − p collisions dominate the VHE outcome.

Conclusions. We are able to reproduce the spectrum of Cyg X-1 during the observed flare under reasonable assumptions. The flare may be the first event of jet-cloud interaction ever detected at such high energies.

Key words. X-rays: binaries – gamma-rays: general – radiation mechanisms: non-thermal – stars: winds, outflows

1. Introduction

Five X-ray binaries have been detected in the very high-energy region of the electromagnetic spectrum, E ~ TeV. Three of them, PSR B1259-63, LS 1 +61 303 and LS 5039, have been detected at different orbital phases and show variable emission. Four gamma-ray flares were detected by the AGILE satellite from the exceptional X-ray binary Cyg X-3 (Tavani et al. 2009). The Fermi Large Area Telescope (LAT) has also detected a variable high-energy source coinciding with the position of Cyg X-3 (Abdo et al. 2009). The fifth source, Cyg X-1, has been detected only once during a flare episode. This latter detection constitutes the first evidence of very high-energy gamma-ray emission produced in the surroundings of a stellar-mass black hole (BH) in our galaxy (for further discussion see Paredes 2008).

Recently, Albert et al. (2007) reported the results from observations of Cyg X-1 at very high energies, E > 200 GeV, performed with the Major Atmospheric Gamma Imaging Cherenkov (MAGIC) telescope. No persistent emission was detected, but a fast transient episode was. The satellites INTEGRAL and Swift/BAT detected with some delay a related flare at hard X-rays, while only a statistically poor detection was found in the RXTE/ASM data at soft X-rays. This wavelength-dependent behavior may suggest that different emitting regions were involved. The gamma-ray excess occurred at orbital phase φ = 0.91. This can help to set constraints on the location of the emission region. More recently, the flaring nature of Cyg X-1 in gamma rays has been confirmed with the AGILE satellite (Sabatini et al. 2010). This work is devoted to a study of the absorption of high-energy photons in Cyg X-1 and the implications of the resulting constraints.

The paper is organized as follows: in the next section we describe the main characteristics of the source under study. Section 3 deals with the gamma-ray opacity by pair creation in the stellar radiation field. The production mechanism of the flare emission is then examined in the context of existing models (e.g. Bosch–Ramon et al. 2006; Romero et al. 2003). In particular, we explore the physical conditions required by the energy budget and spectrum of the flare event. In Sect. 4 we present a simple modelization for the non-thermal emission and compare our calculations with the observational results. Finally, in Sect. 5, we present a brief discussion and the conclusions.

2. Cygnus X-1

The binary system Cyg X-1 is composed by a massive star and a compact object. The X-ray and radio monitoring of the source over the last decades have shown that Cyg X-1 is most of the time in a hard X-ray state and powers collimated jets (e.g. Stirling et al. 2001), which makes it a confirmed high-mass microquasar (HMMQ, Mirabel & Rodríguez 1999). It is located at a distance of 2.2 ± 0.2 kpc (Ziolkowski 2005). The massive star is an O9.7 Iab of 40 ± 10 M⊙ and the compact object is the best-established candidate for a stellar-mass BH in the Galaxy, with
21 ± 8 $M_{\odot}$ (Ziółkowski 2005). The orbit of the system is circular, with a period of 5.6 days and an inclination between 25° and 65° (Gies & Bolton 1986). At radio wavelengths, a semiring surrounds Cyg X-1. This feature is thought to be the result of a strong shock at the location where the jet impacts onto the ambient interstellar medium (Gallo et al. 2005).

Regarding the flare event at VHEs, the observed energy spectrum is well fitted by a relatively soft power law (Albert et al. 2007)

$$\frac{dN}{dAddE} = (2.3 \pm 0.6) \times 10^{-12} \times \left(\frac{E}{1\,\text{TeV}}\right)^{-3.2 \pm 0.6} \text{cm}^{-2} \text{s}^{-1} \text{TeV}^{-1}. \quad (1)$$

The star provides an intense radiation field that can absorb gamma-rays by pair creation within the binary system. The detection by MAGIC occurred near the superior conjunction, when this opacity to gamma-ray propagation from a region close to the compact object is expected to be maximum.

The massive star has a strong wind. Considerable observational evidence supports the idea that winds of high-mass stars are clumpy (e.g. Owocki & Cohen 2006; Moffat 2008). In a HMMQ, some clumps could eventually penetrate into the jet of the system enhancing the non-thermal emission, as proposed by Owocki et al. (2009).

3. Gamma-ray opacity due to $e^+e^-$ pair creation in the stellar radiation field

3.1. Calculations

In a HMMQ the radiation field of the massive star provides soft photons that can annihilate gamma-rays by pair creation: $\gamma + \gamma \rightarrow e^+ + e^-$. We consider the opacity treatment for gamma-ray absorption in a massive X-ray binary system as in Dubus (2006) and Romero et al. (2007). The differential opacity for a gamma-ray at $P$ traveling in the direction given by $e_\gamma$ due to photons of an energy $\epsilon$ emitted at $S$ in the direction $e_\epsilon$ is (Fig. 1)

$$\sigma_{\gamma\gamma}(\beta) = (1 - e_\epsilon \cdot e_\gamma) n_\epsilon \sigma_{\gamma\gamma} d\epsilon d\Omega dl,$$ \quad (2)

where $d\Omega$ is the solid angle of the surface that emits the photons and $n_\epsilon$ is the specific radiation density.

The cross-section for photon annihilation is (Gould & Schréder 1967)

$$\sigma_{\gamma\gamma}(\beta) = \frac{\pi \alpha^2}{2} (1 - \beta^2)^2 \times \left[2\beta(\beta^2 - 2) + (3 - \beta^2) \ln \left(\frac{1 + \beta}{1 - \beta}\right)\right], \quad (3)$$

where $\beta = (1 - 1/s)^{1/2}$, and $s = E_\epsilon(1 - e_\epsilon \cdot e_\gamma)/(mc^2)^2$. Here, $E_\gamma$ and $\epsilon$ are the energies of the gamma-ray and the stellar photon, respectively. This reaction occurs above a minimum energy given by

$$E_\gamma \epsilon = \frac{2(m c^2)^2}{(1 - e_\epsilon \cdot e_\gamma)^2}, \quad (4)$$

where $e_\gamma$ is a unitary vector in the direction of the gamma-ray propagation and $e_\epsilon$ is also a unitary vector in the direction of the stellar photon propagation. The optical depth is a trajectory integral for which the angular dependence has a very significant effect. The absorption is then highly modulated by the orbital motion. It depends also on the target photon field, which is strongly anisotropic along the gamma-ray path.

Because the massive star completely dominates the spectral distribution of the radiative field at low energies, any other source of radiation for the production of pairs with gamma rays is neglected here. The star has a radius $R_{\star}$, and for simplicity we assume a blackbody density radiation of a temperature $T_{\star}$:

$$n_\epsilon = \frac{2\epsilon^2}{\hbar^2 c^3} \frac{1}{\exp(\epsilon/kT_{\star}) - 1}. \quad (5)$$

The geometry considered for the gamma-ray absorption is shown in Fig. 2. If emission occurs at a height $h$ above the compact object and perpendicular to the orbital plane, the distance $d$ from the star becomes $d = \sqrt{d_0^2 + h^2}$ and the initial angle changes from $\psi_0 = \sin(\theta)\sin(i)$ to $\psi_1$. Note that according to Fig. 2

$$\cos \psi_1 = e_1 \cdot e_{\text{obs}} = \frac{1}{\sqrt{(d_0^2 + h^2)}}(d_0 \cos 2\pi \phi \sin i - h \cos i). \quad (6)$$

The parameters adopted for the calculations are shown in Table 1.
can be seen that the absorption drops strongly as the height above the compact object increases for \( h > 10^{11} \) cm. When \( h < 10^{11} \) cm the absorption does not present major changes, due to the distances involved that make the photon density remain rather constant (i.e. \( R_\star \sim 10^{12} \) cm and \( r_{\text{orb}} = 3.4 \times 10^{12} \) cm; see Fig. 2), Bosch-Ramon et al. (2008) find out from opacity calculations near the superior conjunction that the TeV emitter in Cyg X-1 should be located at a distance greater than \( 10^{12} \) cm above the compact object. Our absorption calculations agree with this result. Notice that our results cover a much larger parameter space.

From Albert et al. (2007) the observed flux is a power law (Eq. (1)), in the energy range between 150 GeV and 3 TeV. Considering that the intrinsic flux from the flare is also a power law \( F_{\text{int}} = \kappa E^{-\alpha} \), we can relate both expressions through

\[
F_{\text{obs}} = F_{\text{int}} e^{-\tau(E)}. \tag{7}
\]

From the computed numerical values of \( \tau(E) \), using the dependence of \( \tau \) on the height \( h \), we obtain the intrinsic spectral index \( \alpha \) as a function of the latter parameter, Figure 5 shows the result. Note that for an altitude of \( h \sim 10^{11} \) cm the de-absorbed and production spectra are essentially the same.

3.2 Results

In Fig. 3 we show a 2D-map of the attenuation coefficient \( e^{-\tau} \) as a function of the energy \( E \) and the height \( h \) above the orbital plane. This absorption map corresponds to the orbital phase \( \phi = 0.91 \), when the flare occurred. As can be seen from the figure, the attenuation is high at energies between 10 GeV and 10 TeV, close to the compact object, which makes the absorption problem in the energy range where MAGIC detected the flare very relevant.

In Fig. 4 we show a 2D-map of the attenuation coefficient for \( E = 1 \) TeV as a function of the orbital phase \( \phi \) and the height \( h \). It can be seen that the absorption drops strongly as the height above

| Parameter [units] | values |
|-------------------|--------|
| \( R_\star \) Stellar radius [cm] | \( 1.5 \times 10^{12} \) |
| \( T_\star \) Stellar temperature [K] | \( 3 \times 10^{4} \) |
| \( r_{\text{orb}} \) Orbital radius [cm] | \( 3.4 \times 10^{12} \) |
| \( \theta \) Viewing angle | \( \pi/6 \) |
| \( M_{\text{BH}} \) BH mass [\( M_\odot \)] | 20 |
| \( h_0 \) Jet initial point [\( R_{\text{orb}} \)] | 50 |
| \( h_{\text{int}} \) Height above compact object [cm] | \( 10^{13} \) |
| \( \phi \) Equipartition parameter | 0.1 |
| \( \Gamma_{\text{jet}} \) Jet bulk Lorentz factor | 1.4 |
| \( B \) Magnetic field [G] | 0.9 |
| \( \eta \) Acceleration efficiency | 0.1 |
| \( L_{\text{jet}} \) Jet kinetic power [erg s\(^{-1}\)] | \( 10^{37} \) |
| \( a \) Hadron-to-lepton energy ratio | 100 |
| \( q_{\text{rel}} \) Jet content of relativistic particles | 5% |
| \( R_{\text{jet}} \) Jet radius [\( h_{\text{int}} \)] | 0.1 |
| \( e \) Thickness of the “one zone” [\( h_{\text{int}} \)] | 0.05 |
| \( \zeta \) Particle injection index | 2.8 |
| \( M_\star \) Stellar mass loss rate [\( M_\odot \) yr\(^{-1}\)] | \( 3 \times 10^{-6} \) |
| \( \varepsilon_{\text{rel}} \) Terminal wind velocity [cm s\(^{-1}\)] | \( 2 \times 10^9 \) |

Notes. Those related to the absorption are listed first.
4. Flare production mechanism

A hadronic MQ model for Cyg X-1 has been already considered in Orellana et al. (2007) based on ideas advanced by Romero et al. (2003). We here revisit that scenario with the addition of the interaction between the steady jet and a more dense target: a clump from the stellar wind that allows through locally generated shocks the reacceleration of the particles that produce VHE emission far from the BH, as in Araudo et al. (2009). The jet-clump system is assumed to be momentarily in steady state. As observed in the stable configuration of a microquasar the VHE emission far from the BH, as in Araudo et al. (2009).

The kinetic energy in the form of relativistic particles is provided by the companion star, considered as a blackbody source. Following Bosch-Ramon et al. (2006) the calculations of the emission are based on the works by Bosch-Ramon et al. (2006) and Romero & Vila (2008). The jet is considered perpendicular to the orbital plane, and a continuous jet. The calculations of the emission are based on the work by Bosch-Ramon et al. (2006) and Romero & Vila (2008). The jet is assumed to be in steady state. As observed in the stable configuration of a microquasar the VHE emission far from the BH, as in Araudo et al. (2009).

The synchrotron losses rate is

\[ \dot{E}_{\text{synch}} = \frac{4 \sigma_T c U_B}{3 m_e c^2} \left( \frac{m_e}{m} \right)^3 \frac{E}{m c^2}, \]

where \( \sigma_T \) is the Thomson cross-section and \( U_B \) is the magnetic energy density.

The IC loss rate can be calculated from (Blumenthal & Gould 1970)

\[ \dot{E}_{\text{IC}} = \frac{1}{E_e} \int_{\epsilon_{\min}}^{\epsilon_{\max}} \int_{\Omega} \epsilon^{1/2} f(q) \frac{dN}{de \Omega}, \]

where \( \epsilon \) and \( \epsilon_1 \) are the incident and scattered photon energies, respectively, and

\[ f(q) = 2 q \ln q + (1 + 2q)(1 - q) + \frac{1}{2} \left( b_1 q \right) \left( 1 - q \right). \]

Here \( b_1 = 4 \epsilon_1 / m c^2 \) and \( q = \epsilon_1 / [b(E_e - \epsilon_1)] \). The seed photon field is provided by the companion star, considered as a blackbody at \( T_e \) and is transformed to the jet reference frame (Dermer & Schlickeiser 2002)

\[ n_{e,\Omega} = \frac{n_e}{\Omega (1 + \beta \mu)^2}, \]

where \( \Gamma_J \) is the jet Lorentz factor, \( \Omega \) represents the photon direction, \( \mu = \cos \Theta \), and \( \Theta \) is the angle between the photon direction and the jet axis (the quantities with primes are in the jet RF). We considered the “head on” approximation, in which \( \mu \approx -1 \).

The relativistic Bremsstrahlung losses for a completely ionized plasma were computed according to (Berezinskii et al. 1990)

\[ \dot{E}_{\text{rel}} = 4 n Z^2 e^2 \alpha c \ln \left( \frac{2 E_e}{m_e c^2} - 1 \right), \]
where \( n = n_{\text{wind}}/\Gamma \) is the density of target ions expressed in the jet RF. For external Bremsstrahlung the target-ion density is that of the stellar wind ions (the wind is considered as a completely ionized plasma). At a height \( h \)

\[
n_{\text{wind}}(h) = \frac{M_*}{4\pi v_{\infty} m_p (h^2 + c^2)} \left( 1 - \frac{R_*}{\sqrt{h^2 + r_{\text{orb}}^2}} \right)^{-1},
\]  

(18)

where \( v_{\infty} \) is the terminal velocity of the wind (e.g. Romero et al. 2003 and references therein). In order to take into account the mixing between the jet and the background wind material in a phenomenological way, we introduced a penetration factor \( f_p = 0.3 \) (Romero et al. 2005). The clump is considered as a condensation of the wind with a density of \( \sim 10^{14} \text{ cm}^{-3} \). Notice that particle rejection at the jet-wind boundary is considered only for the background wind. The clump is assumed to fully penetrate the jet (see Araudo et al. 2009 for details). For internal Bremsstrahlung the target-ion density is the proton density of the jet, directly derived from \( m_{\text{jet}}/\Gamma c \).

Relativistic protons lose energy through adiabatic expansion, synchrotron radiation, and by losses produced by hadronic interactions. The energy loss rate produced by proton-proton interactions is

\[
\frac{dE_{p}}{dt}_{\text{pp}} = n_p c \sigma_{\text{pp}} K_{\text{pp}},
\]

(19)

where \( n_p \) is the density of target protons and \( K_{\text{pp}} \) the inelasticity (\( \sim 0.5 \)). The cross-section can be approximated (Kelner et al. 2006) by

\[
\sigma_{\text{pp}} = (34.3 + 1.88 L + 0.25 L^2) \left[ 1 - \left( \frac{E_{\text{inh}}}{E_p} \right)^{1/2} \right]^2 \text{mb},
\]

(20)

where \( L = \ln (E_p/1 \text{ TeV}) \). Photomeson production is not considered because the stellar photons do not have enough energy to reach the threshold energy of this process.

In Fig. 6 we show the rates of cooling and energy gain for electrons and protons in the acceleration region, which is considered to be the bow-shock between the jet and the clump. The electrons reach TeV energies while the protons can attain energies \( \sim 10^2 \text{ TeV} \).

In the one zone approximation the steady state particle distributions \( N(E) \) result from the transport equation (Ginzburg & Syrovatskii 1964)

\[
\frac{\partial}{\partial E} \frac{dE}{dt}_{\text{loss}} N(E) + \frac{N(E)}{\tau_{\text{esc}}} = Q(E),
\]

(21)

where \( \tau_{\text{esc}} \sim h_{\text{int}}/\tau_{\text{jet}} \).

The exact analytical solution of the equation is

\[
N(E) = \frac{1}{N(E)} \int_{E}^{E_{\text{max}}} dE' Q(E') \exp \left( -\frac{\tau(E, E')}{\tau_{\text{esc}}} \right),
\]

(22)

with

\[
\tau(E, E') = \int_{E}^{E'} dE'' \left| \frac{dE''}{dt}_{\text{loss}} \right|^{-1}.
\]

(23)

The particle injection function, \( Q(E) \), is assumed to be a power-law in the energy of the particles,

\[
Q(E) = Q_0 E^{-\zeta},
\]

(24)

This distribution is expected to be the result of diffusive particle acceleration by the reverse shock. The index \( \zeta \) is taken as 2.8 for both types of particles, in accordance with the obtained results shown in Fig. 5. The normalization constant \( Q_0 \) for each type of particle is derived from \( L_{e, p} \) as

\[
L_{e, p} = V \int_{E_{\text{min}}}^{E_{\text{max}}} dE_{e, p} E_{e, p} Q_{e, p}(E_{e, p}),
\]

(25)

where \( V \) is the co-moving one-zone volume.

### 4.1. Radiative processes

We consider synchrotron emission from both electrons and protons, inverse Compton emission from electron interactions with the stellar photon field, internal and external relativistic Bremsstrahlung, and inelastic collisions between relativistic protons in the jet and the cold material that forms the jet, plus with the matter of the clump and the background wind. We checked that the emission produced by secondary particles is negligible, as well as the synchrotron self-Compton (SSC).

The synchrotron emission was computed with the approximation

\[
L_{\gamma}(E_{\gamma}) = \frac{E_{\gamma} V \sqrt{3 e^3 B}}{\hbar c^2} \int_{E_{\text{min}}}^{E_{\text{max}}} dE N(E) \frac{E_{\gamma}}{E_c} 1.85 \times \left( \frac{E_{\gamma}}{E_c} \right)^{1/3} \exp \left( -\frac{E_{\gamma}}{E_c} \right).
\]

(26)
where
\[ E_e = \frac{3 \epsilon h B}{4 \pi m_e c^2} \left( \frac{E}{m_e c^2} \right)^2, \] (27)
and the usual meaning for the constants \( c, h, \epsilon \).

The IC emission by the electron population was calculated as
\[ L_{\text{IC}}(E_e) = E_e^2 V \int_{E_{\text{min}}}^{E_{\text{max}}} dE_e N_e(E_e) \times \int_{\text{min}}^{\text{max}} E_e dP_{\text{IC}}(E_e, E\gamma, \epsilon), \]
where the spectrum of scattered photons is
\[ P_{\text{IC}}(E_e, E\gamma, \epsilon) = \frac{3\epsilon \gamma \epsilon (m_e c^2)^2 n_{\text{ph}}(\epsilon)}{4E_e^3} F(\epsilon), \] (29)
with
\[ F(\epsilon) = 2 \ln q + (1 + 2q)(1 - q) + \frac{1}{2} \left( 1 - q \right) \frac{(q\Omega)^2}{(1 + \epsilon q)}. \] (30)
and \( \Omega = (4E_e^2)/(m_e c^2)^2 \), \( q = (E\gamma)/(\epsilon \Omega (1 - E\gamma/E_e)) \).

The relativistic Bremsstrahlung contribution is given by
\[ L_{\gamma}(E_e) = E_e V \int_{E_k}^{E_{\text{max}}} n_{\gamma}(E_e, E\gamma) \frac{c}{4\pi} N_e(E_e) dE_e, \] (31)
where
\[ \sigma_{\text{B}}(E_e, E\gamma) = \frac{4\alpha \gamma^2}{E_e^3} \phi(E_e, E\gamma), \] (32)
and
\[ \phi(E_e, E\gamma) = \left[ 1 + (1 - E\gamma/E_e)^2 - 2/3(1 - E\gamma/E_e) \right] \times \ln \frac{E_e E\gamma - E_k}{E_k E\gamma - 1} - \frac{1}{2}. \] (33)

All luminosities were calculated in the jet co-moving RF. Photon energies in both frames are related by the Doppler factor \( D \) as
\[ E_e = D E'_{\gamma}, \] (34)
where
\[ D = \frac{1}{\Gamma_{\text{jet}} (1 - \beta_{\text{jet}} \cos \theta_p)}. \] (35)

The luminosity in the observer frame is given by (e.g. Lind & Blandford 1985)
\[ L_\gamma(E_e) = D^2 L'_\gamma(E'_{\gamma}), \] (36)

In order to compute the gamma-ray emission produced by neutral pion decay we note that the \( p-p \) cross-section parametrization (Eq. (20)) is given in the laboratory RF. Then, we convert the flux of relativistic protons to the laboratory frame:
\[ J(E_p, \theta_p) = \frac{A T^{-3(a-1)} E_p^2 \beta \cos \theta_p \sqrt{E_p^2 - m_p c^2}}{4 \pi \sin^2 \theta_p + \Gamma^2} \left( \cos \theta_p - \frac{\beta E_p}{\sqrt{E_p^2 - m_p c^2}} \right)^{2(1/2)}, \] (37)

where \( A \) is a normalization constant. The flux of protons, which is isotropic in the jet RF, is beamed in the lab RF, as indicated by the dependence on the viewing angle \( \theta_p \).

The gamma-ray luminosity, for \( E_p < 0.1 \) TeV, can be obtained straightforwardly as
\[ L_\gamma(E_e) = V E_e^2 2 \int_{E_{\text{min}}}^{E_{\text{max}}} \frac{q(E_e)}{\sqrt{E_e - m_e c^2}} dE_e, \] (38)
with \( E_{\text{min}} = E\gamma + m_e c^2/4E_\gamma \).

Here \( \tilde{n} \) is the total number of \( \pi^0 \) created per \( p-p \) collision.

The gamma-ray luminosity in the range \( 0.1 \) TeV \( \leq E_p \leq 10^5 \) TeV can be obtained from (Kelner et al. 2006)
\[ L_\gamma(E_e) = n_p E_e^2 V \int_{E_{\text{min}}}^{E_{\text{max}}} \sigma_{\text{gr}}(E_p) dE_p \times \frac{F(\gamma, E_p)}{E_{\gamma}}, \] (41)

with \( F(\gamma, E_p) \) a function of \( E_\gamma \) and \( E_p \). For further details on radiative processes see Vila & Aharonian (2009) and references therein.

In order to reproduce the observed spectral energy distribution (SED), the density ratio between the clump and the wind at the base is \( \sim 4.6 \times 10^4 \), i.e. \( n_c \sim 3.3 \times 10^{14} \text{ cm}^{-3} \).

Figure 7 shows the computed SED. We have included the thermal emission by the star, which largely dominates at optical energies. At X-rays, the components of the emission by the accretion disk and a corona should be added to our results. These components in the low-hard state have luminosities \( \sim 10^{35} \text{ erg s}^{-1} \) and extend up to \( \sim 150 \text{ keV} \) (see Romero et al. 2002), in a way that they completely dominate over the non-thermal radiation. The emission from the corona and a non-thermal tail (McConnell et al. 2000; Malzac et al. 2008) are also shown. The model for this emission is from Romero et al. (2010) and is presented in detail elsewhere. Here we show only the results relevant to Cyg X-1.

4.2. Internal absorption

Internal photon-photon annihilation within the region of gamma-ray production can result in strong attenuation of the radiation (Aharonian et al. 2008; Romero & Vila 2008). The opacity is again an integral of Eq. (2), but now considering the locally produced photons with density \( n_{\text{ph}}(\epsilon) \). We can use the symmetry in one of the angles to write
\[ \tau(E_\gamma) = \frac{1}{2} \int_0^{\epsilon_{\text{max}}} \int_{\epsilon_{\text{min}}}^{\epsilon_{\text{max}}} (1 - u) \sigma_{\gamma\gamma}(\beta) n_{\text{ph}}(\epsilon) d\epsilon d\epsilon. \] (42)

Here, \( u = \cos \theta, \theta \) is the angle between the momenta of the colliding photons, \( l \) is the photon path, and the cross-section \( \sigma_{\gamma\gamma}(\beta) \)
is given by Eq. (3). The absorbing photon fields are those generated within the jets (i.e., those calculated in the former section). At energies $E_\gamma \gtrsim 10^{15}$ eV, the dominant absorbing field is the synchrotron radiation from electrons. In the local approximation of Ghisellini et al. (1985),

$$n_{\text{synchr}} \approx \frac{\epsilon_{\text{synchr}}}{\epsilon_c} r_c$$

(43)

where $\epsilon_{\text{synchr}}$ is the synchrotron power per unit volume per unit energy: $\epsilon_{\text{synchr}} = L_\gamma/(\epsilon^2 V)$, with $L_\gamma$ from Eq. (26).

We find that $\tau(E_\gamma)$ is completely negligible (at the level of $\tau \sim 10^{-6}$), implying that the attenuation coefficient is $\sim 1$.

## 5. Discussion

The VHE transient emission of Cyg X-1 occurred when the BH was behind the star with respect to the observer. Because of the high absorption in the flare detection energy range, the emission close to the BH is not enough to explain the observations, unless the photons travel far away from the star, initiating a spatially extended pair cascade as considered by Zdziarski et al. (2008). This requires a fine-tuned magnetic field, which allows the instantaneous isotropization of the electrons, but does not overcome their IC radiative losses. A more realistic/accurate calculation of the electromagnetic cascade propagation is then desirable. Such simulations (following the electron trajectories) will be available in a future work as an application of the code developed by Pellizza et al. (2009).

Previous 1D cascade simulations (Orellana et al. 2007) are consistent with a strong absorption and steep spectrum at TeV energies. The results by Bosch-Ramon et al. (2008) have shown that if the cascades are suppressed by effects of the magnetic field, the synchrotron emission of the secondary pairs peaks at lower energies ($\sim$GeV).

Romero et al. (2002) have suggested that Cyg X-1 could go through occasional microblazar phases and have estimated that the luminosity in the observer RF can be up to one order of magnitude higher than the luminosity in the jet RF. Even taking this into account, a flare triggered at the base of the jet is undetectable due to absorption at phase 0.91. A remaining option could be a very short episode with a highly increased accretion/ejection rate, but this is speculative given the lack of evidence at lower energies supporting the hypothesis.

Under the geometry considered here (a jet perpendicular to the orbital plane, which has an inclination of $\sim 30$ deg), the high-energy emission should have occurred at a large distance above the compact object where the absorbing photon field is diluted. In order to quantify the radiative outcome in this scenario we have considered the interaction of relativistic particles accelerated in a narrow region of the jet with the target particles of a dense clump of the wind.

The flare timescale is related to the permanence of the clump inside the jet. For a spherical clump with a radius $R_c$ smaller than the jet radius $R_{\text{jet}} \sim 10^{12}$ cm we can make a zeroth order estimation of the time that it takes the clump to cross the jet: $t_c$. 

![Fig. 7. Computed SED and the MAGIC observational data from Cyg X-1 (Albert et al. 2007). A two-temperatures corona with a non-thermal component is presented as well. The data are from McConnell et al. (2000). The similar data from Malzac et al. (2008) can be easily fitted (see Romero et al. 2010).](image-url)
The clump velocity is the wind velocity, which at this height is simply \( v_\infty \):

\[
t_c \approx 2R_{\text{jet}}/v_\infty \sim 10^4 \text{ s.}
\]

The flaring episode had a timescale shorter than one day and a rising time of about one hour, which is on the same order as the \( t_c \) estimated.

The simple model presented here for the broadband spectrum of Cygnus X-1 reproduces fairly well the observed SED by MAGIC during the flare using a set of parameters that agrees with reasonable values for this source. Interactions between the clumpy winds of massive stars with the relativistic jets in HMMQ are expected to produce flaring episodes at high and very high energies, and may be detectable by the new high-energy detectors, like Fermi, MAGIC II, and VERITAS.
