Abstract. Swimming is important for promoting and maintaining health, as it can increase the efficiency of the cardiovascular system and decrease the occurrence of cardiovascular diseases. The objective of the present study was to examine whether swimming training could decrease myocardial injury in rats caused by myocardial ischemia/reperfusion (I/R). Sprague-Dawley rats were randomized into four groups, namely the Sham, coronary artery occlusion, swimming training and ischemic preconditioning (IPC) groups. Myocardial I/R was induced in anesthetized male Sprague-Dawley rats by a 40-min occlusion followed by a 3-h reperfusion of the left anterior descending coronary artery. The rats were sacrificed after surgery and their hearts were examined. The results demonstrated that the number of TUNEL-positive nuclei and degree of caspase-3 activation were both significantly increased in the myocardium following myocardial I/R in rats, indicating increased cardiomyocyte apoptosis. On the other hand, swimming training decreased the serum levels of creatine phosphokinase, lactate dehydrogenase and cardiac troponin I, and was associated with reduced histological damage and myocardial infarct size. Furthermore, swimming training also reduced TNF-α levels, caspase-3 activation and enhanced Bcl-2 activation, which decreased the number of apoptotic cells in the myocardium. The findings of the present study showed that swimming training and IPC could similarly decrease myocardial injury following myocardial I/R, and may therefore be used as exercise training to effectively prevent myocardial injury.

Introduction

The World Health Organization (2019) reported that heart disease, stroke and other cardiovascular diseases are the most frequent causes of death, with ischemic heart disease (IHD) accounting for the largest number of cardiovascular diseases-related deaths (1,2). The Global Burden of Disease (GBD) study from 2016 stated that IHD and stroke are both types of cardiovascular diseases, and cardiovascular diseases overall are categorized as the leading cause of death in humans (2).

IHD refers to heart disease caused by insufficient blood circulation due to coronary artery stenosis, which manifests as decreased blood perfusion of the heart, resulting in myocardial ischemia, decreased metabolism and abnormal cardiac function (3,4). When the vascular diameter decreases or occlusion occurs due to coronary artery endothelial cell thickening, lipid deposition or thrombosis, an imbalance develops between myocardial oxygen supply and demand, which further causes cardiomyocyte apoptosis or necrosis (5). Therefore, cardiac blood flow should be restored as soon as possible after myocardial ischemia to prevent myocardial necrosis; however, myocardial ischemia/reperfusion (I/R) also damages cardiomyocytes, which is termed myocardial I/R injury (MIRI) (6). MIRI is known to be associated with the incidence and mortality rate of cardiovascular diseases (7), as the myocardium develops biochemical and metabolic alterations during I/R. These include rapid intracellular ATP exhaustion, calcium overload leading to cell membrane disruption, synthesis of a large number of reactive oxygen species (ROS) and a decreased mitochondrial membrane potential, leading to caspase-3 activation and myocardial hypercontracture (8-11), thereby leading to cardiomyocyte death.

Ischemic preconditioning (IPC), one of the most common methods used to decrease the severity of myocardial injury in myocardial infarction (MI) studies, refers to administration of transient non-lethal infarction stimulation prior to the occurrence of fatal myocardial ischemia events. This stimulation induces immune system mechanisms and releases endogenous protective substances, such as adenosine, bradykinin and nitric oxide, to protect the myocardium and preserve energy metabolism, thereby decreasing the damage caused as well as the risk of fatal infarction (12,13). IPC in vivo has predominantly been performed in animal studies, and the earliest study by Murry et al (14) found that IPC could protect the myocardium against persistent ischemic injury and reduce the infarct size (14-17). Subsequently, several studies have employed IPC in a number of animal experiments, such as rabbit, rat, murine and swine animal models, and proved that IPC protected the

Key words: swimming training, myocardial ischemia-reperfusion, ischemic preconditioning, coronary artery occlusion, apoptosis

Exercise is key for promoting and maintaining human health. Regular aerobic exercise can promote metabolism, improve hormone equilibrium, improve cognitive function, and it is also an important factor that controls cardiovascular disease (22,23). It is well known that exercise can improve systemic circulation to increase cardiopulmonary function, increase coronary artery perfusion and improve cardiac tolerance (24-26).

It was previously demonstrated that exercise can be beneficial to myocardial function, as it can increase the ventricular dimensions, myocardial mass, cardiac output and stroke volume (27,28). The effect of exercise training on MI was first evidenced in the study by McElroy et al (29). They found that the formation of new blood vessels in the hearts of rats after exercise reduced the infarct size after MI. In animals, running on a treadmill and swimming are primarily employed as interventional methods. For example, rats that undergo treadmill training are shown to have improved recovery in blood pumping capacity following myocardial ischemia, and they also exhibit increased levels of cardiac antioxidant enzymes, which decrease lipid peroxidation (30,31). Swimming can increase cardiac antioxidant capacity in rats and improve the systolic function of the aged myocardium. In addition, swimming training prior to MI can increase cardiac arteriole density and aid in improving cardiac function at the remodeling phase (32-34).

Reducing cell death and myocardial injury caused by IHD and MIRI has been an important focus of research. Mitochondrial dysfunction following MIRI can induce apoptotic cell death, since the mitochondrial apoptogenic factor, cytochrome c, is released into the cytoplasm to activate caspase-3-mediated apoptosis (35); however, cytochrome c leakage to the cytosol can be inhibited by Bcl-2/Bcl-xL (36). Furthermore, myocardial I/R causes the release of TNF-α, which is a proinflammatory cytokine that exacerbates MIRI at an early stage of reperfusion by activating NF-xB, facilitating leukocyte infiltration and inducing apoptosis (37,38). Animal experiments were performed in the present study to examine whether exercise intervention could protect against cardiovascular disease and to explore the roles of apoptotic signaling elements, such as TNF-α, activated caspase-3 and Bcl-2. The findings of the present study may lead to optimization of exercise programming for healthy individuals, athletes and patients with heart failure seeking strategies to enhance cardiac function (39).

**Materials and methods**

**Ethics approval.** The present study was approved by the Animal Experiment Committee of University of Taipei (Taipei, Taiwan; IACUC approval no. UT110001). The animals used in the study were managed in a humane manner in accordance with the Guide for the Care and Use of Laboratory Animals (40).

**Animal preparation.** A total of 42 Sprague-Dawley male rats, which were purchased from BioLASCO, and weighed 250-280 g, were used in the present study. A total of 1 week prior to the experiment, the rats were moved to the laboratory to allow them to acclimate. The rats were given ad libitum access to food and water, and maintained with a 12 h light/dark cycle from 6:00 a.m. to 6:00 p.m., and the room temperature was controlled at 25˚C and a humidity of 55±5%.

The rats were randomly assigned to one of four groups as follows: Sham control group (Sham, n=10), myocardial ischemia group (coronary artery occlusion; CAO, n=10), swimming training group (EXC, n=10) and IPC group (IPC, n=10). Rats in the EXC group were allowed to acclimate to swimming training at the age of 3 weeks. Swimming started at 15 min per day and was increased to 180 min per day at day 6. At 4-7 weeks of age, the rats underwent 3 h of swimming training per day. Water temperature was controlled at 35-37˚C. The forced swimming test procedure was employed for swimming training (41). Since the forced swimming test procedure was employed in the swimming training, the rats were kept in the status of swimming throughout the training period in which they could not reach the bottom or hang on the side with the continued supervision of the experimenters. In other words, the time of immobility and climbing while the rats in the water was completely excluded.

**Experimental protocol.** The rats were anesthetized by intraperitoneal injection of 20 mg/kg BW Zoletil 50 [tiletamine + zolezepam; Virbac (Taiwan) Co., Ltd.] and intraperitoneal injection of 10 mg/kg BW Balanzine (xylazine 2% w/v) (42). After tracheotomy, each rat was intubated and ventilated, and the carotid artery was cannulated for the direct BP measurement. Throughout the experiment, heart rate, systolic blood pressure (SBP), diastolic blood pressure (DBP), and mean arterial pressure (MAP) were recorded using a direct measurement method through the carotid artery with a Biopac MP150 (Biopac Data Acquisition System). The purpose of detecting hemodynamic changes was to observe the heart condition of each group of experimental rats before, during and after the experiment. Electrocardiography leads were placed on limbs. After median sternotomy, a 4-0 silk suture was passed around the proximal part of the left anterior descending coronary artery. The ends of the silk suture were threaded through a small vinyl tube to form a snare. The body temperature was monitored using a rectal thermometer and maintained at 37˚C with heating pads throughout the experiments.

After achieving hemodynamic stability for 20 min, the rats were divided randomly into four groups. Group 1 rats (Sham) underwent the same surgical procedures without any pretreatment, CAO or reperfusion. Group 2 rats (CAO) did not receive any pretreatment. Group 3 rats (EXC) underwent 4 weeks of swimming training intervention prior to surgery. In group 4 rats (IPC), IPC was induced via two 10-min episodes of CAO. The two episodes of CAO were followed by 10 min of reperfusion. At 10 min after the previously mentioned treatments, a 40-min CAO was induced in the rats in groups 2, 3 and 4 by pulling the snare around the left anterior descending coronary artery. Successful occlusion was verified by observing the development of ST segment elevation and changes in the QRS complex on the electrocardiogram and cyanotic changes in the myocardium in the occluded area. After 40 min of CAO, the snare was released for reperfusion for 3 h. Reperfusion was confirmed by refilling of the coronary artery and visualizing a...
reactive hyperemic response. Arterial pressure, heart rate and electrocardiography were recorded simultaneously and continuously throughout the experiment. The grouping flowchart is shown in Fig. 1. After the operation, rats were euthanized by exsanguination. Blood specimens were collected from the carotid artery and serum separated after centrifugation (2,000 x g at 4°C for 20 min) for biochemical research.

**Determination of the area at risk (AAR) and MI size.** The dyeing methods of Zhao et al (43) were followed. After the experiment was completed, heparin (1,000 U) was injected intravenously. Subsequently, the heart was resected and the previous MI site was re-ligated. Next, 1% Evans blue dye (MilliporeSigma) was perfused into the ascending aorta. After perfusion was completed, five transverse sections were made through the left ventricle and interventricular septum. The sections were immersed in 1% triphenyl tetrazolium chloride solution and heated in a 37°C thermostatic water bath for 20 min. After heating, the sections were weighed, and 10% formalin solution was added to fix the sections at room temperature for 24 h. The colors of blue, pale and red respectively represented the normal, infarcted and ischemic tissue. The total weight of the AAR and MI were calculated and the sum was taken. AAR is defined as the myocardial tissue within the vascular territory that is distal to the culprit lesion of the infarct-related artery. MI is the percentage of the weight of the red area divided by the weight of the left ventricle; MI is the percentage of the weight of the white area divided by the red area (44).

**Biochemical analysis of cardiac function.** Blood was collected from rats in each group after the experiment was completed. The levels of troponin I, lactate dehydrogenase (LDH) and creatine phosphokinase (CPK) were subsequently measured. CPK and LDH activities were determined according to standard methods using diagnostic kits from BioSystems S.A. Assessment of serum troponin I was carried out via enzyme-linked immunosorbent assay (ELISA) using a commercial kit purchased from DRG International, Inc. According to standard methods using diagnostic kits from BioSystems S.A. Assessment of serum troponin I was carried out via enzyme-linked immunosorbent assay (ELISA) using a commercial kit purchased from DRG International, Inc. The concentration of troponin-I, LDH and CPK in the blood was measured. CPK and LDH activities were determined and converting the value to a percentage by dividing it by the total number of the cell nuclei.

**Histological examination of the heart.** At the end of the experiment, the hearts from four rats in each group were harvested. Part of the heart was fixed using 10% paraformaldehyde at room temperature for 24 h, dehydrated, embedded in paraffin, cut into 4-µm sections and mounted on glass slides. The sections were then deparaffinized using xylene at room temperature for 10 min, and counterstained using hematoxylin and eosin (H&E) at room temperature for 7 min. Finally, the samples were analyzed using an inverted light microscope (CKX53; Olympus Corporation) at x400 magnification. The severity of myocardial injury was determined using a morphological scoring system as follows: 0, no damage; 1, interstitial edema and focal necrosis; 2, diffuse myocardial cell swelling and necrosis; 3, necrosis with contraction bands and neutrophil infiltrate; and 4, widespread necrosis with contraction bands, neutrophil infiltrate and hemorrhage. The evaluation of the myocardial damages based on the HE staining was the average of the scores from two separate examiners (46). To make comparisons between groups, the mean score and standard deviation of each group was calculated.

**TUNEL staining analysis of the heart.** Briefly, when the experiments were completed, the hearts were cut into 4-µm sections and fixed in acetone at room temperature for 24 h. Then, the samples were moved into a solution containing terminal deoxynucleotidyl transferase and detection buffer (Roche Diagnostics GmbH), conjugated with horseradish peroxidase, and incubated at 37°C for 60 min. A diamino-benzidine-chromogen (Boehringer) was used. Several further steps were introduced to obtain the end value of the number of TUNEL-positive nuclei, including the samples were analyzed using an inverted light microscope (CKX53; Olympus Corporation) at x400 magnification, then selecting an area randomly, counting the nuclei in that area, and converting the value to a percentage by dividing it by the total number of the cell nuclei.

**Western blot analysis.** Briefly, when the experiments were completed, the hearts of four rats from each group were moved into the tissue protein extraction reagent (T-PER; Thermo Fisher Scientific, Inc.) at 4°C for homogenization; the myocardial cell lysate was prepared in cold lysis buffer [25 mM Tris-HCl (pH 7.6), 150 mM NaCl, 1% NP-40, 1% sodium deoxycholate, 0.1% SDS]. Samples were centrifuged at 10,000 x g at 4°C for 10 min, and a modified Bradford assay which compared with the conventional Bradford method was used to determine protein concentrations. Notably, the characteristics are stable, the measurement speed is fast, the sensitivity is high and the error rate is small. A total of 60 µg of protein were loaded and separated using 15% SDS-PAGE and then transferred to a nitrocellulose membrane. After blocking with 5% non-fat dry milk in Tris-buffered saline containing 0.1% Tween-20 (TBST) at 37°C for 30 min, the membranes
were incubated with anti‑caspase‑3 (cat. no. IMG‑144A; 
Imgenex), anti‑TNF‑α (cat. no. sc‑52746; Santa Cruz Biotechnology) or anti‑Bcl‑2 antibodies (cat. no. 633502; 
BioLegend; all 1:1,000) in 5% non‑fat dry milk at 4°C for 24 h. 
The membranes were then incubated in 5% non‑fat dry milk in 
TBST containing secondary antibody (m‑IgGx BP‑HPR; 
cat. no. sc‑516102; Santa Cruz Biotechnology; 1:1,000) conjugated 
to horseradish peroxidase. To visualize the peroxidase 
activity, an enhanced chemiluminescence substrate system was 
used, followed by exposing the membranes to hyperfilms. 
β‑actin (cat. no. 643802; BioLegend; 1:1,000) was used at 
room temperature for 2 h as a loading control. ImageJ 
version 1.6 (National Institutes of Health) was used for densi 
tometry analysis, and each gel was normalized against the 
background density.

Capillary density measurements in tissue sections. To visu 
alyze the capillaries in the myocardium, endothelial cells were 
stained with CD31, often used as a biological marker to repre 
sent the capillary vessels in the myocardium. Angiogenesis 
was quantitatively assessed based on CD31‑positive capillary 
vessels for the determination of capillary density. For immu 
nostaining, a rabbit anti‑rat CD31 antibody (cat. no. sc‑376764; 
Santa Cruz Biotechnology; 1:100) was used at room tempera 
ture for 15 min. Staining was visualized by reaction with DAB (MilliporeSigma; 1:20). Capillaries were visualized in 
the myocardium as a brown precipitate, identified as having a 
diameter <20μm and a layer of endothelial cells without smooth 
muscle cells. Computer‑assisted morphometry was performed 
using Image Pro Plus version 5.0 (Media Cybernetics, Inc).

Statistical analysis. Data are presented as the mean ± stan 
dard deviation, and statistical analysis was performed using 
SPSS 20.0 (IBM Corp.). Hemodynamic variables were 
analyzed using a two‑way repeated measures ANOVA. 
Otherwise, data were analyzed using one‑way ANOVA and 
a Bonferroni post hoc multiple comparisons test. The ordinal 
values of the myocardial injury scores were analyzed using 
a Mann‑Whitney U test. P<0.05 was considered to indicate a 
statistically significant difference.

Results

Comparison of mortality rates amongst the four groups. A 
total of 42 rats were used in the present study. Of those 42 rats, 
1 rat in the CAO group died from heart failure, which was 
declared as a progressive decrease of the systolic arterial pres 
ture to <50 mmHg with global left ventricular dilatation and 
poor contraction; and 1 rat in the IPC group developed ventric 
ular fibrillation and died. These two rats were excluded from 
the study. No statistically significant difference was observed 
amongst the four groups in terms of mortality rate (P=0.591).

Comparison of changes in hemodynamic variables during the 
experiments amongst the four groups. No significant differ 
ence was found amongst the four groups in terms of mean 
arterial pressure and heart rate, at baseline and throughout 
the experiments. In addition, the changes in hemodynamic 
variables did not reach a level of statistical significance during 
the experiments in the four groups (Table I).

Comparison of AAR and MI size amongst the CAO, EXC and 
IPC groups. When the experiments were completed, six rats 
from each group were randomly selected to collect cardiac 
tissues for AAR and MI size analysis. The AAR of the left 
ventricular infarct area is shown in Fig. 2A. The MI size, 
expressed as a percentage of AAR, is shown in Fig. 2B. The 
results demonstrated that there was no statistically significant 
difference in AAR amongst the three groups (50.44±1.75% in 
CAO vs. 49.90±1.62% in EXC and 49.29±0.88% in IPC; 
P>0.05), while the MI size was significantly decreased in the 
EXC and IPC experimental groups compared with the CAO 
group (20.27±0.88% in EXC and 19.37±0.95% in IPC vs. 
28.15±1.54% in CAO; P<0.001).

Intervention with EXC and IPC significantly reduces the 
serum concentrations of troponin I, LDH and CPK after 
myocardial I/R. When the experiments were completed, 
six rats from each group were randomly selected to collect 
blood samples for biochemical analysis of cardiac function. 
CAO group rats, compared with Sham group rats, exhibited 
significantly increased serum levels of troponin I (298.08±173.09 ng/ml vs. 0.68±0.47 ng/ml, respect 
ively; P<0.05; Fig. 3A), LDH (4,606.17±1,057.12 U/l vs. 
259.83±127.48 U/l, respectively; P<0.001, Fig. 3B) and CPK 
(8,531.33±591.00 U/l vs. 577.50±19.40 U/l, respectively; 
P<0.001, Fig. 3C). The EXC and IPC groups exhibited 
significantly lower serum levels of troponin I (41.56±10.44 and 41.31±9.23 ng/ml, respectively, vs. 
the CAO group; P<0.05; Fig. 3A), LDH (1,496.33±292.03 and 1,351.83±265.11 U/l, respectively, vs. the CAO group; 
P<0.001; Fig. 3B) and CPK (3,918.17±1,761.22 and 3,867.00± 
755.85 U/l, respectively, vs. the CAO group; P<0.01; Fig. 3C). 
No significant differences between the EXC and IPC groups were 
observed (P>0.05).

EXC and IPC interventions significantly reduces MIRI. At 
the end of the experiments, four rats from each group were 
randomly selected, and part of their hearts was sent for histo 
logical examination in order to identify cardiac injury. The 
myocardium in the left ventricle of the rats in the Sham group 
appeared normal  (Fig. 4A); however, the myocardium of rats 
in the CAO group exhibited myocardial I/R.

Intervention with EXC and IPC significantly reduces the 
small portion of the hearts of the rats in the Sham group 
with the CAO group rats, compared with Sham group rats, 
expressed as a percentage of AAR, is shown in Fig. 2B. The 
results demonstrated that there was no statistically significant 
difference in AAR amongst the three groups (50.44±1.75% in 
CAO vs. 49.90±1.62% in EXC and 49.29±0.88% in IPC; 
P>0.05), while the MI size was significantly decreased in the 
EXC and IPC experimental groups compared with the CAO 
group (20.27±0.88% in EXC and 19.37±0.95% in IPC vs. 
28.15±1.54% in CAO; P<0.001).

Intervention with EXC and IPC significantly reduces the

\textsuperscript{a}Data are presented as the mean ± standard deviation. Baseline 1, baseline prior to IPC; Baseline 2, baseline after ischemic preconditioning; CAO, coronary artery occlusion; CAR, coronary artery reperfusion; MAP, mean arterial pressure; EXC, swimming training; IPC, ischemic precondition.
exhibited TUNEL-stained nuclei (Fig. 5A). With regard to the rats in the CAO group, heart samples were also found to exhibit TUNEL staining, which was induced by myocardial I/R. In the EXC and IPC groups, dark brown staining was observed in the heart samples in the form of scattered nuclei. There was a significant increase in the percentage of the TUNEL-positive nuclei against the total nuclei in the hearts of the rats from the CAO group compared with the Sham group (34.4±5.5% vs. 2.3±0.7%, respectively; P<0.001; Fig. 5B), and the corresponding percentages in the EXC and IPC groups were decreased significantly (19.7±1.2 and 19.0±1.5%, respectively, vs. the CAO group; P<0.05; Fig. 5B). No significant difference in the numbers of TUNEL-positive nuclei between the EXC and IPC groups was observed (Fig. 5B).

**EXC and IPC interventions significantly reduces the levels of TNF-α and activated caspase-3, and increases the levels of Bcl-2 in cardiomyocytes.** TNFs are a family of cellular signaling proteins that are involved in systemic inflammation, and are some of the most critical pro-inflammatory cytokines (48). Activated caspase-3 is a universal effector of apoptosis (49), and Bcl-2 is an important gene family that controls the primary apoptotic pathway (49). To measure the levels of TNF-α, activated caspase-3 and Bcl-2, four rats from each group were randomly selected and western blot analysis on their heart samples was conducted at the end of the experiments. Compared with the Sham group, myocardial I/R significantly increased the TNF-α levels in the hearts of the rats in the CAO group (P<0.001; lane 2, Fig. 6A). The EXC and IPC groups exhibited a significantly less prominent increase
in TNF-α levels in the hearts subjected to myocardial I/R (P<0.001 vs. CAO group; lanes 3 and 4, Fig. 6A). There was no significant difference in TNF-α expression between the EXC and IPC groups (Fig. 6A). Caspase-3 is cleaved to an active p17 subunit (17 kDa) when apoptosis is induced. According to the results of western blot analysis, which showed a significant increase in the activated caspase-3 band, it was inferred that myocardial I/R could increase the levels of activated caspase-3 in the hearts (P<0.001 vs. Sham group; lane 2, Fig. 6B); conversely, the increase in activated caspase-3 was significantly inhibited in the EXC and IPC groups (P<0.001 vs. CAO group; lanes 3 and 4, Fig. 6B). No significant difference in the activated caspase-3 expression between the EXC and IPC groups was observed (Fig. 6B). Compared with the Sham group, CAO group hearts exhibited a significant reduction in Bcl-2 levels (P<0.001 vs. Sham group; lane 2, Fig. 6C), while this decrease in Bcl-2 levels was significantly inhibited in the EXC and IPC groups (P<0.001 vs. CAO group; lanes 3 and 4, Fig. 6C). No significant difference in the Bcl-2 expression levels between the EXC and IPC groups was observed (Fig. 6C).

EXC significantly increases the density of myocardial blood vessels. At the end of the experiments, four rats from each group were randomly selected, and part of their hearts were used for CD31 staining analysis in order to identify the density of myocardial blood vessels. Compared with the Sham,
CAO and IPC groups, the EXC group exhibited a significant increase in the density of myocardial blood vessels (P<0.001 vs. SHAM, CAO and IPC groups; Fig. 7).

Discussion

In the present study, it was demonstrated that swimming training could significantly decrease myocardial injury, MI size, serum concentrations of MI markers (troponin I, CPK and LDH) and cardiomyocyte apoptosis following a myocardial I/R, and the myocardial protective effects were even comparable to those of the commonly used method of IPC.

The intense and sustained changes of myocardial injury that occur during the myocardial ischemic period lay the foundation for the reperfusion injury that follows. This type of I/R injury has been proven to be an extension of ischemic injury, which further exacerbates irreversible myocardial injury (44,46). Therefore, strategies for preventing reperfusion injury are the important aspect of treatment of related heart diseases. Previous studies have proven that IPC can significantly decrease MI size, DNA laddering, the number of TUNEL-stained nuclei and cardiomyocyte apoptosis to exert cardioprotective effects (50,51).

It has been demonstrated that the cardioprotective effects of IPC can be exerted in two temporal windows. The first is active within minutes to hours after the conditioning stress; the second, known as ‘second window of protection’, becomes active 1-3 days later (52,53). The mechanisms underlying training-induced cardioprotection resemble those elicited by IPC, whereby short ischemic episodes prior to a major ischemic insult trigger endogenous cardioprotective mechanisms. Training may induce IPC by emulating minor local ischemic episodes, with ischemia occurring as short periods of time during which the supply of blood and oxygen to tissues is limited with respect to the tissue requirements (54).

The experimental results of the present study revealed that MI size was significantly decreased after myocardial I/R in rats that underwent swimming training. There was no significant difference in AAR among the three groups (groups 2-4) and no significant hemodynamic changes were observed during the surgical procedure. Therefore, reduced MI size could not be attributed to differences in surgical technique or hemodynamic changes.

Intermittent hypoxia is broadly defined as repeated episodes of hypoxia interspersed with episodes of normoxia. The definition of intermittent hypoxia varies widely in terms of cycle length, number of hypoxic episodes per day and the number of days of exposure. Nevertheless, it has been confirmed that repeated incidents of ischemia and hypoxia may lead to physiological changes and are considered as one of the key factors involved in cardiovascular diseases, general inflammation and heart disease (55,56).

Intermittent hypoxia primarily affects the cardiac structure and function via oxidative damage caused by free radicals (57). Myocardial I/R disrupts the mitochondrial respiratory chain and is accompanied by ATP depletion, resulting in the accumulation of mitochondrial ROS (51). The effects of IPC are mediated through activating K_{ATP} channels in the mitochondria. Once activated, the progress of phosphorylation in mitochondria is accelerated, which results in a reduction in ATP consumption in mitochondria, i.e., a reduction in the metabolic rate in cells (58). ROS levels increase during exercise; however, mounting epidemiological data have proven that exercise decreases the incidence of
oxidative stress-associated diseases owing to exercise-induced adaptation (59,60). Exercise training can protect cardiac subsarcolemmal and intermyofibrillar mitochondria, enabling them to adapt to transient hypoxia and decreasing ROS production, increasing their ability to tolerate high calcium levels, and preventing oxidative damage caused by myocardial I/R to achieve cardioprotection (61,62). In addition, mitochondria contain an antioxidant enzyme known as Mn superoxide dismutase (MnSOD) that can decrease intracellular oxidative stress (63). The cytoplasm also possesses a Cu/ZnSOD that has a function similar to MnSOD (64). Research indicates that IPC can exert protective effects through the induction of MnSOD. In addition, the levels of MnSOD and Cu/ZnSOD were found to be increased in rat cardiomyocytes after exercise training, which inhibited apoptosis (65,66). Therefore, it may be hypothesized that myocardial antioxidant effects induced by exercise can decrease myocardial injury and cellular damage, thereby reducing MI size.

When cardiomyocytes are exposed to ischemia or hypoxia, the mitochondrial matrix shrinks, leading to an enlargement of the intermembrane space and resulting in a disorientation of cardiomyocytes and disruption of the myocardial structure, and a release of endocardial substances (67). In addition, ischemia in the myocardium can cause the membrane potential of mitochondria to dissipate, leading to an increase in the permeability and an opening in mitochondrial permeability transition pore (mPTP), resulting in a release of apoptosis-inducing factors from mitochondria (67). Therefore, the evaluation of cardiomyocyte injury could be performed by determining the plasma levels of specific and sensitive biomarkers, such as troponin I, CPK and LDH (68-70). It has been found that IPC, by activating protein kinase C, can open K
ATP channels, reduce the release of myocardial enzymes by reducing the consumption of ATP, and create an inflow of potassium ions and other ions, which may help the myocardium reach a balance in osmotic pressure and potential equilibrium, so as to mitigate myocardial injury (71). Theoretically, the cardioprotective effects of exercise may be attributed to the fact that exercise training induces a mitochondrial phenotype, including increases in the protein levels of primary antioxidant enzymes in both subsarcolemmal and interfibrillar mitochondria, attenuation of ROS-induced cytochrome c release, and reduced maximal rates of mPTP opening (72,73). Furthermore, the ratio of blood vessels/muscle fibers increases in healthy hearts after exercise intervention. In addition, exercise training in advance can also increase angiogenesis after MI (74,75). Similar results were obtained in the present study, which showed that swimming intervention increased angiogenesis in the heart. The results of the present study showed that cardiomyocytes released troponin I, LDH and CPK into the blood after I/R. Therefore, these three enzymes were found to be significantly elevated in the CAO group. On the other hand, there were significantly lower levels of the aforementioned three enzymes in the EXC and IPC groups compared with those in the CAO group. Therefore, it can be deduced that exercise training decreased I/R-induced damage by exerting cardioprotective effects through protecting myocardial mitochondria, increasing myocardial vascularization and maintaining cardiomyocyte integrity, thereby decreasing the release of the aforementioned enzymes. In addition, examination of HE-stained myocardial sections revealed that the myocardium exhibited deformation and expansion, and the muscle fibers were arranged in a disorderly manner after myocardial I/R, and these changes were significantly reduced following treatment intervention with EXC and IPC.

The free radicals produced during myocardial I/R can activate NF-κB. Subsequently, TNF-α, which induces the transcription of NF-κB, can directly damage vascular endothelial cells and cardiomyocytes (76). Functionally, TNF-α could trigger cellular responses via interacting with its transmembrane receptors, such as TNF receptor 1 (TNFR1) (77). Upon activation by TNF-α, TNFR1 can activate the death induction signal mediated by TNF receptor-associated death domain and Fas-associated death domain in order to activate caspase-3, -6 and -8, and reduce the production of the anti-apoptotic protein Bcl-2, eventually causing apoptosis (78,79).

**Figure 7.** Myocardial tissue angiogenesis. (A) Representative images of CD31 staining. Magnification, x400. Arrows indicate muscle actin-positive micro vessels. (B) Quantitative morphometric analysis of arteriole density. n=4. ***P<0.001. CAO, coronary artery occlusion; EXC, swimming training; IPC, ischemic preconditioning.
NF-κB is a family of inducible transcription factors that serve a variety of evolutionarily conserved roles in the immune system. Cytokines belonging to the TNF family induce rapid transcription of genes regulating inflammation, cell survival, proliferation and differentiation, primarily through activation of the NF-κB pathway (80). IPC can induce mild oxidative stress on cells, which can activate NF-κB and induce Bcl-2, which in turn reduce the extent of cardiomyocyte damage and apoptosis during the subsequent I/R process (81). Exercise can trigger short-term inflammation, alongside an increase in white blood cells, oxidative stress and the levels of C-reactive protein (CRP). Regular exercise reduces CRP, IL-6 and TNF-α levels, and also increases the levels of anti-inflammatory factors, such as IL-4 and IL-10 (82). The results of the present study demonstrated that the concentration of TNF-α in the myocardial cells of both EXC and IPC group rats decreased significantly, indicating that exercise reduced the concentration of TNF-α and reduced the inflammatory and apoptotic responses to achieve cardioprotective effects.

Apoptosis and necrosis are two types of cell death induced by myocardial I/R. Apoptosis-related genes, such as those of the Bcl-2 or caspase families, are known components of the signaling pathway controlling apoptosis. The caspase family is a protease system that directly causes apoptosis. Activation of both the extrinsic and the intrinsic apoptotic pathway results in cleavage of caspase-3, which activates the execution phase of apoptosis (82). Bcl-2 enhances proton release from the mitochondria and exerts a regulatory effect on the opening of the mPTP, and therefore has an anti-apoptotic effect (83). Caspase-3 is activated by intracytoplasmic release of mitochondrial proteins, such as cytochrome c and apoptosis-inducing factor, which is restrained by Bcl-2 and Bcl-xL upstream of caspase. Furthermore, the expression of antiapoptotic genes, such as Bcl-2 or Bcl-xL, is activated by the suppression of the transcription factor NF-κB, which restrains apoptosis (81). It was previously demonstrated that IPC could attenuate caspase-3 activation and increase Bcl-2 performance (84,85). These findings suggest that prevention of caspase activation may contribute to myocardial protection.

The heat shock response is a common cellular reaction to external stimuli, such as ischemia, hypoxia, acidosis, oxidative stress, protein degradation, increased intracellular calcium and energy depletion; therefore, IPC can also activate the release of heat shock proteins (HSPs) (86,87). Exercise also increases the expression of cardiac HSPs, as a variety of stressors associated with exercise, including heat stress and hypoxia, reduced intracellular pH, ROS and reactive nitrogen species production, depletion of glucose and glycogen stores, increase in cytosolic calcium levels and cardiomyocyte stretching, can all contribute to HSP elevation in cardiac muscle (88). The protective effects of HSPs on cardiomyocytes include maintenance of myocardial calcium ion concentration and a decrease in the release of pro-inflammatory factors. HSPs can also regulate ATP synthesis in the mitochondria and affect signal transduction through the MAPK/JNK pathway to inhibit apoptosis and increase the anti-apoptotic capacity in cardiomyocytes (89-91). Certain researchers even consider HSPs, in addition to Bcl-2, as a type of anti-apoptosis protein (90,92,93). The present study found that, in addition to a smaller infarct size in the EXC and the IPC groups, the extent of apoptosis and the expression of caspase-3 in cardiomyocytes decreased considerably, while the expression of Bcl-2 in cardiomyocytes in both groups increased substantially. By inference, this may result from an increase in HSP levels after swimming training and preconditioning of the rats, which strengthens the effect of cardioprotection induced by exercise, so as to improve the endurance of cardiomyocytes to ischemia and hypoxia, resulting in less severe MIRI. Future studies may combine measuring HSPs levels with other related signaling elements such that the cardioprotective mechanism of exercise can be further elucidated.

In this study, histomorphology, blood biochemistry, TUNEL staining and cardiomyocyte TNF-α, caspase-3, and Bcl-2 expression were used to measure the severity of MIRI. The results proved that swimming for 3 h daily for 4 continuous weeks before MI decreased MI size, myocardial injury and cardiomyocyte apoptosis after myocardial I/R to achieve cardioprotective effects that were comparable to IPC. In the future, swimming training can be included in health promotion to decrease mortality rates due to cardiovascular diseases and improve the health of people.
