Practical quantum networks require low-loss and noise-resilient optical interconnects as well as non-Gaussian resources for entanglement distillation and distributed quantum computation. The latter could be provided by superconducting circuits but existing solutions to interface the microwave and optical domains lack either scalability or efficiency, and in most cases the conversion noise is not known. In this work we utilize the unique opportunities of silicon photonics, cavity optomechanics and superconducting circuits to demonstrate a fully integrated, coherent transducer interfacing the microwave X and the telecom S bands with a total (internal) bidirectional transduction efficiency of 1.2% (135%) at millikelvin temperatures. The coupling relies solely on the radiation pressure interaction mediated by the femtometer-scale motion of two silicon nanobeams reaching a $\Delta V$ as low as $16 \mu V$ for sub-nanowatt pump powers. Without the associated optomechanical gain, we achieve a total (internal) pure conversion efficiency of up to 0.019% (1.6%), relevant for future noise-free operation on this qubit-compatible platform.
arge scale quantum networks will facilitate the next level in quantum information technology, such as the internet did for classical communication, enabling, e.g., secure communication and distributed quantum computation. Some of the most promising platforms to process quantum information locally, such as superconducting circuits, spins in solids, and quantum dots, operate naturally in the gigahertz frequency range, but the long-distance transmission of gigahertz radiation is relatively lossy and not resilient to ambient noise. This limits the length of supercooled microwave waveguides in a realistic scenario to tens of meters. In contrast, the transport of quantum information over distances of about 100 km is nowadays routinely achieved by sending optical photons at telecom frequency through optical fibers.

There is a variety of platforms, which in principle have shown to be able to merge the advantages of both worlds ranging from mechanical, piezoelectric, electro-optic, magneto-optic, rare-earth, and Rydberg atom implementations. So far, the optomechanical approach has been proven to be most efficient, reaching a record high photon conversion efficiency of up to 47% with an added noise photon number of only 38. But this composite device is based on a Fabry–Perot cavity that has to be hand assembled and utilizes a membrane mode that is restricted to relatively low mechanical frequencies. Using piezo-electricity, coherent conversion between microwave and optical frequencies has been shown uni- and bidirectional at room temperature and, at low temperatures with integrated devices, so far with either low efficiency or unspecified conversion noise properties. The electro-optic platform has shown promising photon conversion efficiencies recently up to 2% at 2 K, but generally requires very large pump powers in the milliwatt range.

In this work we present a device that converts coherent signals between 10.5 GHz and 198 THz at millikelvin temperatures via the radiation pressure interaction. Due to the need of only picowatt range pump powers, both the heat load to the cryostat and local heating of the integrated device is minimized. The chip-scale device is fabricated from CMOS compatible materials on a commercial silicon-on-insulator wafer over an area of ~200 μm × 120 μm. It is compact, versatile and fully compatible with silicon photonics and superconducting qubits. The unique electro-opto-mechanical design is optimized for very strong field confinement and radiation pressure couplings, which enable internal efficiencies exceeding unity for ultra-low pump powers. We find that the conversion noise so far precludes a quantum limited operation and we present a comprehensive theoretical and experimental noise analysis to evaluate the potential for scalable and noise-free conversion in the future. Such a power-efficient, ultra-sensitive, and highly integrated hybrid interconnect might find applications ranging from quantum communication and distributed quantum computation, where the long-distance transmission of gigahertz radiation is relatively lossy and not resilient to ambient noise, to magnetic resonance imaging.

The electro-optic platform has shown promising photon conversion efficiencies recently up to 2% at 2 K, but generally requires very large pump powers in the milliwatt range. To achieve high quantum efficiency or unspecific conversion noise properties. The electro-optic platform has shown promising photon conversion efficiencies recently up to 2% at 2 K, but generally requires very large pump powers in the milliwatt range.

In this work we present a device that converts coherent signals between 10.5 GHz and 198 THz at millikelvin temperatures via the radiation pressure interaction. Such a power-efficient, ultra-sensitive, and highly integrated hybrid interconnect might find applications ranging from quantum communication and distributed quantum computation, where the long-distance transmission of gigahertz radiation is relatively lossy and not resilient to ambient noise, to magnetic resonance imaging.

Transducer design. We realize conversion by connecting an optomechanical photonic crystal zipper cavity with two aluminum coated and mechanically compliant silicon nanostrings as shown in Fig. 1c. The mechanical coupling between these two components is carefully designed (see Supplementary Note 2), leading to a hybridization of their in-plane vibrational modes into symmetric and antisymmetric supermodes. In case of the anti-symmetric mode that is used in this experiment, the strings and the photonic crystal beams vibrate 180° out of phase as shown by the finite-element method simulation in Fig. 1d. The photonic crystal cavity features two resonances at telecom frequencies with similar optomechanical coupling strength. The simulated spatial distribution of the electric field component $E_x(x, y)$ of the higher frequency mode with lower loss rate used in the experiment is shown in Fig. 1e. The lumped element microwave resonator consists of an ultra-low stray capacitance planar spiral coil inductor and two mechanically compliant capacitors with a vacuum gap of size of ~70 nm. This resonator is inductively coupled to a shorted coplanar waveguide, which is used to send and receive microwave signals from the device. The sample is fabricated using a robust multi-step method including electron beam lithography, silicon etching, aluminum thin-film deposition, and hydrofluoric vapor acid etching, as described in detail in ref. 30.

Transducer characterization. Standard sample characterization (see Supplementary Notes 3 and 4) reveals an optical resonance frequency of $\omega_o/(2\pi) = 198.081$ THz with total loss rate $\kappa_o/(2\pi) = 1.6$ GHz and waveguide coupling rate $\kappa_{ex,o}/(2\pi) = 0.18$ GHz leading to a coupling efficiency of $\eta_o = 0.11$. When the optical light is turned off, the microwave resonance frequency is $\omega_m/(2\pi) = 10.5$ GHz with coupling efficiency $\eta_m = 0.4$ and $\kappa_{ex,m}/(2\pi) = 1.15$ MHz. The mechanical resonator frequency has a value of $\omega_m/(2\pi) = 11.843$ MHz with an intrinsic decoherence rate $\kappa_o/(2\pi) = 15$ Hz at a mode temperature of 150 mK. The achieved single-photon-phonon coupling rates are as high as $\kappa_{ex,m}/(2\pi) = 67$ Hz and $\kappa_{ex,o}/(2\pi) = 0.66$ MHz.

Conversion measurements. To perform coherent photon conversion, red-detuned microwave and optical tones with powers $P_{(e)}$ are applied to the microwave and the optical resonator. These drive tones establish the linearized electro- and optomechanical interactions, which results in the conversion of a weak

\[
\hat{H}_{\text{int}} = \sum_{j=e,o} \left( \hbar G_j (\hat{a}_j \hat{b} + \hat{a}_j^\dagger \hat{b}^\dagger) + \hat{H}_{\text{CR,j}} \right),
\]

where $\hat{a}_j$, $\hat{b}$ with $j = e, o$ is the annihilation operator of the electromagnetic (mechanical) mode, and $\hat{H}_{\text{CR,j}} = \hbar G_j (\hat{a}_j \hat{b} e^{2\pi i n_{j,c}} + \text{h.c.})$ describes the counter-rotating terms which are responsible for the coherent amplification of the signal. $G_j = \sqrt{\hbar G_{0,j}}$ is the parametrically enhanced electro- or optomechanical coupling rate where $n_{j,c}$ is the intracavity photon number due to the corresponding microwave and optical pump tones. For a red-detuned drive in the resolved-sideband regime, the transducer consists of one microwave and optical pump tones. For a red-detuned drive in the resolved-sideband regime, the transducer consists of one microwave and optical pump tones.
microwave (optical) signal tone to the optical (microwave) domain measured in our setup as shown in Fig. 1f. We experimentally characterize the transducer efficiency by measuring the normalized reflection $|S_j|^2 (j = e, o)$ and the bidirectional transmission $\zeta := |S_{oe}|S_{eo}$ coefficients as a function of signal detuning $\delta_j$. As shown in Fig. 2a, for drive powers $P_e = 601$ pW and $P_o = 625$ pW with drive frequencies $\omega_{d,j}$ and detunings $\Delta_j = \omega_j - \omega_{d,j}$ of $\Delta_e = \omega_m$ and $\Delta_o/(2\pi) = 126$ MHz leading to intracavity photon numbers of $n_{d,e} \approx 9 \times 10^3$ and $n_{d,o} \approx 0.2$ with cooperativities $C_e \approx 0.57$ and $C_o \approx 0.9$, the measured total (waveguide to waveguide) photon transduction efficiency is $\approx 1\%$ corresponding to $96.7\%$ internal (resonator to resonator) photon transduction efficiency over the total bandwidth of $\Gamma_{\text{conv}}/(2\pi) \approx 0.37$ kHz. In the case of $\kappa_e > 4\omega_m$ and $\kappa_o < 4\omega_m$, the bandwidth is given by $\Gamma_{\text{conv}} \approx (C_e + 1)\gamma_m$ because the nonsideband resolved optomechanical cavity does not induce mechanical broadening. The signal tone adds $17(10^{-3})$ photons to the microwave resonator (optical cavity).

Here we use a self-calibrated measurement scheme that is independent of the gain and loss of the measurement lines as described in ref. 31 and we only take into account transduction between the upper two sidebands at $\omega_{d,j} + \omega_m$ as shown in Fig. 1b. Neglecting the lower optical sideband that is generated due to the nonsideband resolved situation $\kappa_e/4\omega_m \approx 30$ reduces the reported mean bidirectional efficiencies by $\sqrt{2}$ compared to the actually achieved total transduction efficiency between microwave and optical fields. The observed reflection peaks indicate that both resonators are undercoupled, equivalent to an impedance mismatch for incoming signal light. All scattering parameters are obtained from measured coherent tones whose linewidths are given by the chosen resolution bandwidth and the stability of the heterodyne setup. While this does not explicitly show long term phase stability of the conversion we find that these results are in excellent agreement with our coherent conversion theory model (solid lines) with $\gamma_m$ as the only free fit parameter.

---

**Fig. 1 Silicon photonic microwave-to-optics converter.** a Diagram showing the microwave ($\delta_e$), mechanical ($\delta_m$), and optical ($\delta_o$) mode, and the relevant coupling and loss rates of the device. Scattering parameters $S_{e/o}$ characterizing the transducer performance are indicated. b Schematic showing the frequencies of the coherent signals involved in the conversion process (green arrows). On the left an optical input signal (IS) is converted to an upper sideband (US) of the microwave pump signal, whereas in the microwave-to-optics conversion on the right also the lower sideband (LS) is created. The bidirectional transduction $\zeta$ is only evaluated between the upper sidebands at $\omega_{d,j} + \omega_m$. c Scanning electron micrograph of the device showing the microwave lumped element resonator with an inductively coupled feed line, the photonic crystal cavity, and the optical coupling waveguide fabricated on a fully suspended 220 nm thick silicon-on-insulator device layer. White scale bar, 10 μm. d Simplified experimental setup. The device is mounted on the mixing chamber plate of a cryogen-free dilution refrigerator at a temperature of $T_{\text{ridge}} = 50$ mK. A microwave switch selects between the incoming microwave and optical signal to be analyzed by the ESA. Optical heterodyning is used to detect the low power levels used in the experiment. SG microwave signal generator; ESA electronic spectrum analyzer; VOA variable optical attenuator; SSB EOM single-sideband electro-optic modulator; AOM acousto-opto-optic modulator.
The transduction efficiency with respect to microwave pump power for fixed $P_e = 601\text{ pW}$ and microwave (red, $P_e = 625\text{ pW}$) pump tones. f Intrinsic mechanical decoherence rate $\gamma_m$ versus optical (blue, $P_e = 601\text{ pW}$) and microwave (red, $P_e = 625\text{ pW}$) pump powers extracted from (c) and (d) with Eq. (3) and $\gamma_m$ as only fit parameter. Solid lines in (f) are linear fits to the data.

Figure 2b shows the total transduction efficiency for different pump power combinations with microwave and optical pump powers ranging from 30 to 953 pW and 48 to 1561 pW, respectively. Figure 2c, d shows the efficiency versus $P_e$ ($P_o$) for fixed microwave (optical) pump power $P_e = 601$ ($P_o = 625$) pW. As expected, the transduction efficiency rises with increasing pump powers and reaches a maximum of $\zeta = 1.2\%$. The internal transduction efficiency is significantly higher ($\langle \eta, \eta_o \rangle \leq 135\%$) because both the microwave resonator as well as the optical cavity are highly decoupled with coupling ratios of $\eta_o = 0.11$ and $\eta_e$ ranging between 0.07 and 0.18 when both pumps are on. The increase in the intrinsic loss rate of microwave $\kappa_{mic}$ and mechanical resonator $\kappa_o$ at higher pump powers are shown in Fig. 2e and f caused by considerable heating related to (especially optical) photon absorption. This results in the degradation of the microwave and mechanical quality factors and consequently reduces the waveguide coupling efficiency, the cooperativeness and the total transduction efficiency (see Supplementary Note 5).

Sideband resolution and amplification. In the nonsideband resolved limit the quantum contribution of the rotating term of the Hamiltonian $H_{\text{fr},\omega}$ is nonnegligible, resulting in a transduction process that cannot be fully noise- free. This interesting effect can be correctly described by introducing an amplification of the signal tone with (in the absence of thermal noise) quantum limited gain $G_a$ (see Supplementary Note 1). In contrast, the microwave resonator is in the resolved-sideband condition $4\omega_m > \kappa_o$, so that the signal tone amplification due to electromechanical interaction is negligible $\zeta \simeq 1$. This results in the total power independent, bidirectional conversion gain of $\mathcal{G} = G_a G_a \simeq G_a$, which turns out to be directly related to the minimum reachable phonon occupation:

$$\langle n \rangle_{\min} = \frac{(\Delta_o - \omega_m)^2 + \kappa_o^2/4}{4\Delta_o \omega_m} = G_a - 1,$$

induced by optomechanical quantum backaction when the mechanical resonator is decoupled from its thermal bath. Due to this amplification process the measured transduction efficiency in Fig. 2a is about 110 times larger than one would expect from a model that does not include gain effects for the chosen detuning, and adds the equivalent of at least one half of a vacuum noise photon to the input of the transducer in our case of heterodyne detection (for $\eta_o = 1$ and $\gamma_m \geq 1$). However, it turns out that this noise limitation, which might in principle be overcome with efficient feedforward, sideband suppression, or sideband resolution, accounts for only about 0.1% of the total conversion noise observed in our system. The total transduction (including gain) can be written in terms of the susceptibilities of the electromagnetic modes $\chi_x^{-1}(\omega) = i(\Delta_o - \omega) + \kappa_o/2$ and the mechanical resonator $\chi_m^{-1}(\omega) = i(\omega_m - \omega) + \gamma_m/2$ as:

$$\zeta = \frac{\sqrt{\kappa_o \kappa_{exo}}}{G_a G_a \left(\Delta_o - \omega_m + \chi_m - \chi_o\right)^2} \left[1 + \frac{\left(\chi_m - \chi_o\right)^2}{G_a^2 (\chi_e - \chi_o) + G_b^2 (\chi_o - \chi_e)}\right].$$

Equation (3) can be decomposed into a product of the conversion gain $\mathcal{G}$ and the pure conversion efficiency $\theta$, i.e., $\zeta = \mathcal{G} \times \theta$, for frequencies in the vicinity of $\omega_m$ (see Supplementary Note 1). Equation (2) shows that the signal amplification depends only on the resonator linewidth and the detuning and is not directly related to the $a_1^\dagger b^\dagger$ interaction term or the pump power. This can be understood by the alternative interpretation that the gain represents the ratio of the transduced upper sideband to the difference between upper and lower sideband at each cavity. Therefore, it is instructive to measure the transducer parameters as a function of optical pump detuning as shown in Fig. 3a. While changing the optical detuning, we also vary the pump power in order to keep the optical intracavity photon number constant at $n_{\text{d.o}} = 0.185 \pm 0.015$. This way it is possible to investigate the influence of $\Delta_o$ at a constant optomechanical
coupling \( G_\theta = \frac{g_{\theta \omega}}{\sqrt{n_{\text{d.o}}}} \). The measured total transduction efficiency is shown in Fig. 3a and reaches \( \zeta \approx 1\% \) at \( \Delta_\theta \approx 0 \) for the chosen pump powers in agreement with Fig. 2c, d. We can now separate the measured transduction (Eq. (3)) into conversion gain and pure conversion, as shown in Fig. 3b. The gain shows the expected steep increase at \( \Delta_\theta \to 0 \) where the pure conversion \( \theta \) approaches zero for equal cooling and amplification rates. Around \( \Delta_\theta = \kappa_\theta / 2 \) on the other hand, where \( \langle n \rangle_{\text{min}} \) reaches its minimum of roughly \( \kappa_\theta / 4\omega_\text{in} \approx 30 \), also the gain reaches its minimum and the noiseless part (at zero temperature) of the total (internal) conversion process shows its highest efficiency of \( \theta = 0.019\% \) \((\theta / \eta_{\text{in}}) = 1.6\%\).

**Added noise.** Another important figure of merit, not only for quantum applications, is the amount of added noise quanta\(^{36}\), usually an effective number referenced to the input of the device. For clarity with regards to the physical origin and the actual measurement of the noise power, in the following we define the total amount of added noise quanta \( n_{\text{add,j}} \) added to the input signal \( S_{\text{in,j}} \) after the transduction process as \( S_{\text{out,j}} = S_{\text{in,j}} + n_{\text{add,j}} \). Figure 4a, b shows the measured conversion noise \( n_{\text{add,j}} \) as a function of frequency \( \delta_\ell \) for the same powers and detunings as in Fig. 2a. At these powers our device adds \( n_{\text{add,e}}(\omega) = 224(145) \) noise quanta to the output of the microwave resonator (optical cavity), corresponding to an effective input noise of \( n_{\text{add,j}}/\zeta \). The noise floor originates from the calibrated measurement system and in case of the microwave port to a small part also from an additional broadband resonator noise, cf. Fig. 4b. The solid lines are fits to the theory with the mechanical bath occupation \( \bar{n}_m \) as the only fit parameter (see Supplementary Note 4).

The fitted effective mechanical bath temperature as a function of pump powers is shown in Fig. 4c. It reveals the strong optical pump dependent mechanical mode heating (blue), while the microwave pump (red) has a negligible influence on the mechanical bath. Fig. 4d shows the measured total added noise at the output of the microwave resonator and optical cavity as a function of optical pump power. The noise added to the optical output (blue) increases with pump power due to absorption heating and increasing optomechanical coupling rate \( G_\theta \), while the degradation of the resonator-waveguide coupling efficiency \( \eta_e \) explains the decreasing \( n_{\text{add,e}} \) at higher optical powers for the microwave output noise (red), see Fig. 2e. The intersection of the two noise curves occurs at \( \zeta_c \approx \zeta_0 \) with cooperativities \( \zeta_c \) as defined above, and shows that the optical and microwave resonators share the same mechanical thermal bath. The power dependence is in full agreement with theory (solid lines) and demonstrates that the thermal mechanical population is the dominating origin of the added transducer noise.

**Discussion**

In conclusion, we demonstrated an efficient bidirectional and chip-scale microwave-to-optics transducer using pump powers orders of magnitude lower than comparable all-integrated\(^{11,13,15}\) approaches. Low pump powers are desired to limit the heat load of the cryostat and to minimize on-chip heating, which is
particularly important for integrated devices because of their limited heat dissipation at millikelvin temperatures. Due to the standard material choice involving only silicon and aluminum, our device can be easily integrated with other elements of superconducting circuits as well as silicon photonic and phononic devices in the future.

The two main challenges ahead are the reduced pure conversion efficiency and the optical heating that adds incoherent noise to the converted signal. We expect that both can be solved with design improvements in combination with new measurement techniques. Specifically, starting from the observed pure efficiency of 0.019% a factor of up to nearly two orders of magnitude could be gained with better waveguide coupling geometries in combination with fabrication optimization, e.g., by using surface cleaning and the reduction of humidity. Improving the side-band resolution by increasing the mechanical frequency could yield another factor of up to 25 assuming the same cooperativities can be achieved. Going to the high cooperativity limit would then yield the remaining fraction needed for unity total conversion efficiency. This will certainly require a very effective mitigation of the optical pump power dependent mechanical heating and the associated linewidth degradation that is also required for noise-free conversion. Nevertheless, with better chip thermalization, reduced optical absorption and low duty cycle pulsed measurements this should be feasible. Moreover, it has already been shown that pulsed pump-probe type experiments together with high efficiency heralding measurements can be used for post-selecting rare successful conversion or entanglement generation events for low-noise low-efficiency devices.

In terms of near-term classical receiver and modulation applications, an important figure of merit is the voltage required to induce an optical phase shift of $\pi$. We are able to reach a value as low as $V_{2\pi} = 16 \mu V$ (see Supplementary Note 6), comparable with typical zero point fluctuations in superconducting circuits, nearly a factor 9 lower than the previously reported record, and almost 10 times more power efficient than commercial passive and wide-band unidirectional electro-optic modulators at X band gigahertz frequencies.
