Dated: July 6, 2018

We investigate the steady-state Rényi entanglement entropies after a quench from a piecewise homogeneous initial state in integrable models. In the quench protocol two macroscopically different chains (leads) are joined together at the initial time, and the subsequent dynamics is studied. We study the entropies of a finite subsystem at the interface between the two leads. The density of Rényi entropies coincides with that of the entropies of the Generalized Gibbs Ensemble (GGE) that describes the interface between the chains. By combining the Generalized Hydrodynamics (GHD) treatment of the quench with the Bethe ansatz approach for the Rényi entropies, we provide exact results for quenches from several initial states in the anisotropic Heisenberg chain (XXZ chain), although the approach is applicable, in principle, to any low-entangled initial state and any integrable model. An interesting protocol that we consider is the expansion quench, in which one of the two leads is prepared in the vacuum of the model excitations. An intriguing feature is that for moderately large anisotropy the transport of bound-state is not allowed. Moreover, we show that there is a “critical” anisotropy, above which bound-state transport is permitted. This is reflected in the steady-state entropies, which for large enough anisotropy do not contain information about the bound states. Finally, we benchmark our results against time-dependent Density Matrix Renormalization Group (tDMRG) simulations.

I. INTRODUCTION

In recent years, entanglement-related quantities emerged as informative witnesses of the complexity of the quantum many-body wavefunction, both at equilibrium and out of equilibrium. Entanglement is deeply intertwined with the computational cost to accurately describe the quantum many-body wavefunction, both at equilibrium and out of equilibrium.

The Rényi entropies \( S^{(\alpha)} \) are popular entanglement measures for pure states. Given a subsystem \( A' \), they are defined as

\[
S^{(\alpha)} = \frac{1}{1 - \alpha} \ln \text{Tr} \rho_{A'}^\alpha, \quad \text{with } \alpha \in \mathbb{R},
\]

where \( \rho_{A'} \) is the reduced density matrix of \( A' \). The limit \( \alpha \to 1 \) in (1) defines the von Neumann entropy as \( S = -\text{Tr} \rho_{A'} \ln \rho_{A'} \). The knowledge of Rényi entropies for different values of \( \alpha \) gives access to the distribution of the full spectrum of \( \rho_{A'} \) (entanglement spectrum). Importantly, the Rényi entropies can be computed by using quantum and classical Monte Carlo methods, and can be measured in experiments with cold atoms, unlike the von Neumann entropy.

Rényi and von Neumann entropies are key to understand the fundamental physics underlying thermalization in isolated out-of-equilibrium systems, for instance after a quantum quench. This is the standard protocol to drive a system out-of-equilibrium: A system is prepared initially in a low-entanglement state \( |\Psi_0\rangle \), and it is let to evolve with a local Hamiltonian \( H \), such that \( [H, |\Psi_0\rangle\langle\Psi_0|] \neq 0 \). It is by now accepted that for generic systems local properties of the steady-state emerging at late times can be described by the Gibbs (thermal) ensemble, whereas for integrable models one has to use a Generalized Gibbs Ensemble (GGE). Quite generally, the Rényi entropies (and the von Neumann entropy) exhibit a linear growth at short times, which is followed by a saturation at late times. Their short-time behavior reflects the irreversible growth of the complexity of the system after the quench, whereas their steady-state value coincides with generalized (GGE) free energies. These qualitative features, i.e., the linear growth and the saturation behavior, appear to be ubiquitous.

A well-known quasiparticle picture allows to understand the qualitative behavior of the entanglement spreading. In this picture the entanglement growth is the result of the ballistic propagation of entangled pairs of quasiparticles created after the quench. For non-interacting fermion models, the quasiparticle picture is exact in the scaling limit, as it is has been demonstrated in Ref. 44. Remarkably, for integrable interacting models, by complementing the semiclassical picture with thermodynamic knowledge of the steady state, it is possible to describe quantitatively the full-time dynamics of the von Neumann entropy. Unfortunately, a generalization of this result to the Rényi entropies is not available yet, although the Thermodynamic Bethe Ansatz (TBA) can be used to obtain the steady-state Rényi entropies.

Recent years witnessed an enormous interest in quenches from piecewise homogeneous initial conditions. Several techniques have been used, such as Conformal Field Theory.
(CFT), free-fermion methods, field theory methods, integrability, and numerical techniques. For integrable models the recently-developed Generalized Hydrodynamics (GHD) allows for an analytic treatment of these quenches. The standard setup that we consider is depicted in Figure 1. This is the prototypical situation to study quantum transport in one-dimensional system. Two chains $A$ and $B$ are prepared in two macroscopically different states. At $t = 0$ they are connected, and the full system is let to evolve unitarily under a many-body Hamiltonian $H$. In the GHD approach, in the scaling limit of long time $t$ and large distance $x$, at fixed $\zeta \equiv x/t$ (rays in Figure 1) dynamical properties are described by a GGE. However, as of now, only few results have been derived for the entanglement dynamics after quenches from piecewise homogeneous states. Notable exceptions are systems that can be mapped to CFTs in curved spacetime. Also, for free-fermion systems, the full-time dynamics of the entanglement entropies has been derived analytically in Ref. 124. For interacting integrable models a conjecture for the steady-state von Neumann entropy and for the entanglement production rate at short times has been presented in Ref. 64.

However, extending the quasiparticle picture to describe the Rényi entropies after quenches from piecewise homogeneous states remains an open problem. The aim of this work is to provide a step forward in this direction. Here we focus on the steady-state Rényi entropies of a finite subregion $A'$ of length $\ell$ placed next to the interface between $A$ and $B$ (see Figure 1). The key idea is that in the limit $\ell/t \to 0$, the entire subsystem $A'$ should be described by the GGE with $\zeta = 0$, i.e., by the NESS. Thus, following Ref. 40, the density of Rényi entropy has to coincide with that of the GGE Rényi entropy, which can be calculated using the Thermodynamic Bethe Ansatz (TBA). Specifically, the appropriate thermodynamic ensemble that determines the Rényi entropies is obtained by combining the GHD approach for the quench with the results of Ref. 40. By using this method, we investigate the Rényi entropy after quenches in the spin-1/2 anisotropic Heisenberg chain (XXZ chain). We consider several initial states for $A$ and $B$, such as the Néel state and the Majumdar-Ghosh state. However, in principle, our approach is straightforwardly generalizable to any low-entangled initial state and to any integrable model. For all these quenches, we provide robust numerical evidence for our results by using the time-dependent Density Matrix Renormalization Group (tDMRG) method.

Finally, we consider the quench in which $A$ is initially prepared in the ferromagnetic state. After mapping the Heisenberg chain onto a system of interacting fermions confined in a box, this corresponds to the trap-expansion protocol that is routinely performed in cold-atom experiments. For this reason, we term this quench expansion quench.

A remarkable feature of the XXZ chain is that its spectrum contains composite excitations, which consist of bound states of several elementary particles (magnons). The physics of these bound states is receiving constant attention, both theoretically and experimentally. Interestingly, while for generic quenches, the steady-state entropies contain information about all the types of quasiparticles (bound states), this is not the case for the expansion quench, at least in the limit of large anisotropy. Here we show that this reflects that the bound-state transport between the two chain is not possible at large anisotropy. This is an intriguing effect of the interactions, which renormalize the group velocity of the “bare” excitations of the model. Physically, after the expansion quench, the velocities of the bound states created in the bulk of $A$ and $B$ change their sign when approaching the interface, and they are deflected back. This suggests that the expansion quench could be used as a filter to isolate multi-spin bound states. An interesting result is that there is a “critical” anisotropy, below which dynamical properties change abruptly, and the bound-state transport is permitted. We explicitly check this scenario for the expansion of the Néel state and the Majumdar-Ghosh state, although we expect it to happen for a larger class of initial states.

The paper is organized as follows. In section II A and II B we review the Thermodynamic Bethe ansatz (TBA) approach for homogeneous quantum quenches in integrable models, focusing on the steady-state Rényi entropies in section II C. In section III A we review the Generalized Hydrodynamic approach (GHD). In section III B we discuss the steady-state Rényi entropies. In section IV A we present the XXZ chain and the quench protocols. In section IV B and IV C we discuss the expansion quench and its GHD solution, highlighting the absence of bound-state transport for large anisotropy. In section IV D we report some exact results for the expansion entropies of the Néel and the Majumdar-Ghosh state in the limit of large anisotropy. In section IV E we present theoretical predictions for the steady-state Rényi entropies after the expansion quench. Numerical results are presented in section IV F. Finally, these are benchmarked against tDMRG simulations in section V.

II. RÉNYI ENTROPIES AFTER A HOMOGENEOUS QUENCH

Here we summarize the Thermodynamic Bethe Ansatz (TBA) approach introduced in Ref. 40 (see also Ref. 41 and 42) to calculate the steady-state Rényi entropies after a homogeneous quench. First, in section II A we review some general aspects of the TBA approach for integrable models. In section II B we discuss the TBA treatment for quenches. Section II C is devoted to discussing how to calculate the entropies using TBA.

A. Thermodynamic Bethe ansatz (TBA) for integrable models

The distinctive feature of integrable models is that they possess families of well-defined and stable, i.e., having infinite lifetime, quasiparticles. Different quasiparticles are labelled by their quasimomentum (rapidity) that we denote as $\lambda$. A generic eigenstate of a Bethe ansatz solvable model is in a one-to-one correspondence with a set of allowed quasiparticles, which are obtained by solving a system of non-

125–128, 94–98, 104,105
linear algebraic equations known as Bethe equations\textsuperscript{137}. In the thermodynamic limit the rapidities form a continuum, and it is more convenient to work with the rapidity density $\rho$ (particle densities) and the hole densities $\rho^h$, i.e., the density of unoccupied rapidities. Here we defined $\rho \equiv \{\rho_n\}_{n=1}^{N}$, and $\rho^h \equiv \{\rho^h_n\}_{n=1}^{\infty}$, where $n$ labels the different quasiparticle families. Their total number $N$ depends on the model under consideration. For instance, in the XXZ chain with $\Delta \geq 1$, which is the model considered here, there are infinite families of quasiparticle families, i.e., $N = \infty$. For later convenience we also define the total densities $\rho^{(t)}_n$, the densities $\eta_n$, and the filling functions $\vartheta_n$ as

$$
\rho^{(t)}_n \equiv \rho_n + \rho^h_n, \\
\eta_n \equiv \rho^{(t)}_n \rho^{-1}_n, \\
\vartheta_n \equiv [1 + \eta_n]^{-1}.
$$

In any Bethe ansatz solvable model, the particle densities $\rho_n$ are coupled to the $\eta_n$ via the thermodynamic version of the Bethe equations, which read\textsuperscript{137}

$$
2\pi \rho_n (1 + \eta_n) = a_n - \sum_{m=1}^{\infty} a_{nm} * \rho_m. \tag{5}
$$

Here, the functions $a_n(\lambda)$ and $a_{nm}(\lambda)$ are known from the Bethe ansatz solution of the model. For the XXZ chain $a_n$ and $a_{nm}$ are given as\textsuperscript{137}

$$
a_n = \frac{1}{\pi} \sinh(n\eta), \tag{6}
a_{nm} = (1 - \delta_{nm})a_{n-m} + a_{|n-m|+2} + \cdots + a_{n+m-2} + a_{n+m}. \tag{7}
$$

The matrix $a_{nm}$ encodes the scattering between quasiparticles of different families, and with different rapidities. In (5) the symbol $*$ denotes the convolution

$$
f \ast g = \int \, dl \, f(\lambda - \mu)g(\mu). \tag{8}
$$

Any set of densities $\rho$ identifies a thermodynamic macrostate, which corresponds to an exponentially diverging (with size) number of microscopic eigenstates. Any of these eigenstates can be chosen as a finite-size representative of the thermodynamic macrostate. The total number of equivalent microstates is given as $e^{S_{Y\gamma}}$, with $S_{Y\gamma}$ the so-called Yang-Yang entropy\textsuperscript{137}

$$
S_{Y\gamma}(\rho) \equiv L \sum_n \int d\lambda \, \{ \rho^{(t)}_n \ln \rho^{(t)}_n - \rho^h_n \ln \rho^h_n - \rho_n \ln \rho_n \}, \tag{9}
$$

where $L$ is the system size. The Yang-Yang entropy is extensive and it is obtained by summing independently over the quasiparticle families and their rapidity, reflecting, again, the integrability. For systems in thermal equilibrium $S_{Y\gamma}$ is the thermal entropy. For out-of-equilibrium systems, the density of the Yang-Yang entropy of the GGE that describes the steady state is a key ingredient to understand quantitatively the dynamics of the entanglement entropy after the quench\textsuperscript{45,72}.\n
### B. TBA description of homogeneous quenches

Integrable models à la Bethe possess an extensive number of local and quasi-local conserved quantities $Q_k$, i.e., having the property that $[Q_j, Q_k] = 0$, $\forall j, k$, with $Q$ being the hamiltonian. This implies that, due to these conservation laws, in integrable models the out-of-equilibrium dynamics after a quantum quench, and the steady state, are strongly constrained. As a consequence, at late times the system fails to thermalize, i.e., local properties are not described by the Gibbs ensemble. Still, it is now accepted that local and quasi-local properties of the steady state are described by a Generalized Gibbs Ensemble (GGE). The GGE density matrix is obtained by complementing the Gibbs density matrix with the extra conserved quantities $Q_k$, to obtain

$$
\rho_{\text{GGE}} = \frac{1}{Z_{\text{GGE}}} \exp \left( - \sum_k \beta_k Q_k \right). \tag{10}
$$

Here $\beta_k$ is the Lagrange multiplier associated with $Q_k$ and $Z_{\text{GGE}}$ is a normalization constant (GGE partition function). The $\beta_k$ are fixed by imposing that the GGE average of $Q_k$ equals their initial state value as

$$
\text{Tr}(\rho_{\text{GGE}} Q_k) = \langle \Psi_0 | Q_k | \Psi_0 \rangle. \tag{11}
$$

The key idea of the TBA approach for quantum quenches is that GGE expectation values of local and quasi-local observables are described by a carefully chosen thermodynamic macrostate (see section II.A), which can be completely characterized in terms of the initial state expectation values of the conserved quantities (cf. (11)).

We now illustrate how to determine this macrostate by using the TBA. First, in the thermodynamic limit, the expectation value $Q_k$ over a generic thermodynamic macrostate identified by particle and hole distributions $\rho_n$, $\rho^h_n$ is obtained by summing over the quasiparticle families and integrating over their rapidities as\textsuperscript{137}

$$
Q_k = L \sum_n \int d\lambda \, f_{kn}(\lambda) \rho_n(\lambda), \tag{12}
$$

where we introduced the functions $f_{kn}$, and $L$ is the system size. It is convenient to define the generalized driving $g_n$ as

$$
g_n(\lambda) \equiv \sum_k \beta_k f_{kn}. \tag{13}
$$

The driving $g_n$ contains the crucial information about the initial values of the conserved charges, or, equivalently, on $\beta_k$.

To proceed, it is useful to consider the GGE expectation value $\text{Tr}(\rho_{\text{GGE}} \hat{O})$ of a generic local (or quasi-local) observable $\hat{O}$. In the thermodynamic limit the trace over the model eigenstates becomes a functional integral as

$$
\text{Tr} \rightarrow \int D\rho e^{S_{Y\gamma}(\rho)}, \tag{14}
$$

where $S_{Y\gamma}(\rho)$ is the Yang-Yang entropy.
Here $D\rho \equiv \prod_n D\rho_n$ denotes the functional integral over the densities $\rho_n$. The Yang-Yang entropy in (14) takes into account that a thermodynamic macrostate corresponds to an exponentially large number of eigenstates. Using (14), one can write

$$\text{Tr}(\hat{O}\rho_{\text{GGE}}) = \frac{1}{Z_{\text{GGE}}} \int D\rho e^{-\mathcal{E}(\rho) + S_{YY}(\rho)}\langle \rho | \hat{O} | \rho \rangle. \quad (15)$$

Here we defined $\mathcal{E}(\rho)$ as

$$\mathcal{E} = L \sum_n \int d\lambda g_n(\lambda) \rho_n(\lambda). \quad (16)$$

In (15), $\langle \rho | \hat{O} | \rho \rangle$ denotes the value of $\hat{O}$ over the macrostate. Importantly, the locality and quasilocality of $\hat{O}$ implies that $\mathcal{E}$ is extensive, as it is clear from (16). Due to the extensivity of $\mathcal{E}$ and $S_{YY}$, following the standard TBA approach \cite{137}, in the thermodynamic limit the integral in (15) can be treated using the saddle point method. One has to minimize the functional $S_{\text{GGE}}$ defined as

$$S_{\text{GGE}} \equiv -\mathcal{E} + S_{YY}. \quad (17)$$

After minimizing (17) with respect to $\rho_n$, one obtains a set of generalized TBA equations for $\eta_n$ (see (4)) as

$$\ln \eta_n = g_n + \sum_{m=1}^{\infty} a_{nm} \ast \ln(1 + \eta_m^{-1}(\lambda)), \quad (18)$$

where $a_{nm}$ is the same as in (5), and $g_n$ is defined in (13). Finally, the GGE macrostate densities $\rho_n$ are obtained by substituting the solutions of (18) in the TBA equations (5).

### C. TBA approach for Rényi entropies

Here we discuss how to calculate the steady-state value of the Rényi entanglement entropies after a homogeneous quench in integrable systems \cite{140,141}. Since local properties of the steady state are described by a GGE, the density of Rényi entanglement entropies has to coincide with that of the GGE Rényi entropies $S_{\text{GGE}}^{(\alpha)}$. These are defined as

$$S_{\text{GGE}}^{(\alpha)} = \frac{1}{1 - \alpha} \ln \text{Tr}_\rho^{\alpha} \rho_{\text{GGE}}, \quad (19)$$

where $\rho_{\text{GGE}}$ is defined in (10). We now discuss how to calculate (19) using the Thermodynamic Bethe ansatz. Similar to (15), in the thermodynamic limit the GGE Rényi entropies are written as

$$S_{\text{GGE}}^{(\alpha)} = \frac{1}{1 - \alpha} \left[ \ln \int D\rho \exp(-\alpha \mathcal{E} + S_{YY} + \alpha f_{\text{GGE}}) \right], \quad (20)$$

where $f_{\text{GGE}} \equiv -\ln Z_{\text{GGE}}$, $\mathcal{E}$ is the same as in (16), and $S_{YY}$ is the GGE thermodynamic entropy. The functional integral in (20) can be treated using the saddle point method. The functional $S_{\text{GGE}}^{(\alpha)}$ that has to be minimized depends explicitly on the Rényi index $\alpha$, and it is defined as

$$S_{\text{GGE}}^{(\alpha)} \equiv -\alpha \mathcal{E} + S_{YY}. \quad (21)$$

The saddle point condition leads to the modified TBA equations for $\eta_n^{(\alpha)}$ as

$$\ln \eta_n^{(\alpha)} = g_n + \sum_{m=1}^{\infty} a_{nm} \ast \ln(1 + \eta_m^{(\alpha)}). \quad (22)$$

The particle densities $\rho_n^{(\alpha)}$ are obtained by substituting $\eta_n^{(\alpha)}$ in the Bethe equations (5). By combining (21) and (19), one obtains that the density of the Rényi entropies for a GGE is

$$S_{\text{GGE}}^{(\alpha)} = \frac{1}{1 - \alpha} \left[ \left( -\alpha \mathcal{E} + S_{YY} \right) \bigg|_{\eta_n^{(\alpha)} + \alpha f_{\text{GGE}} / \rho_n^{(\alpha)}} \right], \quad (23)$$

where $\rho_n^{(1)}$ is the saddle point densities for $\alpha = 1$ that describes local steady-state properties.

As it is clear from (22), the macrostate describing the Rényi entropies depends on $\alpha$. This is surprising because both the Rényi entropies and the von Neumann entropy are calculated from the same quantum state. An interesting consequence is that the region of energy spectrum of the post-quench hamiltonian that is relevant for describing the Rényi entropies is different from that of describing the local observables. A similar behavior happens for non-integrable models, where it is a consequence of the Eigenstate Thermalization Hypothesis \cite{139}.

At this point it is important to stress that the method to calculate the Rényi entropies that we outlined so far requires as crucial ingredient the set of infinitely many Lagrange multipliers $\beta_k$ entering in the driving functions $g_n$ (cf. (13)). Fixing the $\beta_k$ by using the constraint (11) is a formidable task that cannot be carried out in practice. However, this difficulty can be overcome in two ways. One is to use the Quench Action method \cite{140,141}. The Quench Action provides direct access to the thermodynamic macrostate describing the stationary state. The driving functions $g_n$ are extracted from the overlaps between the initial state and the eigenstates of the post-quench hamiltonian, without relying on the $\beta_k$. Interestingly, a subset of the thermodynamically relevant overlaps is sufficient to determine the macrostate (see (142–144)). For a large class of initial states the overlaps can be determined analytically \cite{145–160}. This holds also for systems in the continuum, such as the Lieb-Liniger gas. For instance, in Refs. \cite{149–151,161}, the overlaps between the Bose condensate (BEC) state and the eigenstates of the Lieb-Liniger model have been calculated, for both attractive and repulsive interactions. Interestingly, a crucial feature of all the initial states for which it has been possible to calculate the overlaps is reflection symmetry. Reflection-symmetric initial states have nonzero overlap only with parity-invariant eigenstates, which are identified by solutions of the Bethe equations containing only pairs of rapidities with opposite sign, i.e., such that $\{\lambda_i\} = \{-\lambda_j\}$. Interestingly, the role played by parity-invariance for the solvability of quantum quenches has been investigated in Ref. \cite{162} for lattice models and in Ref. \cite{163} for integrable field theories. Also, one should remark that non-reflection-symmetric initial states have been found \cite{160} for which the Quench Action method can be applied. We should mention that the knowledge of the overlaps was crucial in Ref. \cite{141} to obtain the steady-state Rényi entropies after the quench from the Néel state. For some quenches
the TBA macrostates describing the steady state can be derived from the expectation values of the conserved quantities over the initial state, without knowing the overlaps. For instance, this is the case for the quench from the tilted Néel state (see, however, Ref. 146 for a recent conjecture for the overlaps). In these cases, one can use the TBA equations (18) to extract the driving functions \( g_n \) from the macrostate densities. The functions \( g_n \) can then be used in the general TBA equations (22) to derive the Rényi entropies. The validity of this approach for homogeneous quenches has been investigated recently in Ref. 42. Crucially, for quenches from piecewise homogeneous initial states, the GGE macrostate describing the local steady-state are determined by solving a continuity equation (see below), and the TBA driving functions are not even defined. This implies that the approach of Ref. 42 has to be employed.

### D. Min entropy of GGE

Before proceeding, it is interesting to consider the limit \( \alpha \to \infty \) of the GGE Rényi entropies, which corresponds to min entropy of the GGE, or the so-called single copy entanglement entropy \( S^{(\infty)} \), which is written in terms of the largest eigenvalues \( \lambda_M \) of the reduced density matrix as \( S^{(\infty)} = -\ln \lambda_M \). For homogeneous quenches in the XXZ chain the steady-state value of the single-copy entanglement has been derived in Ref. 40. An interesting feature is that the thermodynamic macrostate that determines its steady-state value breaks down at sufficiently small values of the chain anisotropy, where \( S^{(\infty)} \) is described by a different macrostate. This new macrostate has zero Yang-Yang entropy and the associated TBA densities \( \rho^{(\infty)}_\alpha \) exhibit a Fermi-sea structure, but it has a non-trivial bound-state content.

We now discuss the TBA derivation of the steady-state value of the min entropy after a homogeneous quenches. The generalization to quenches from piecewise homogeneous initial states is straightforward. First, it is useful to rewrite the TBA densities \( \eta^{(\alpha)}_n \) (cf. (22)) as

\[
\eta^{(\alpha)}_n = \exp(\alpha \gamma_n). \tag{24}
\]

Here the functions \( \gamma_n \) have to be determined by using the TBA equations (22). Clearly, from (24) one has that in the limit \( \alpha \to \infty \), \( \eta^{(\infty)}_n \) (vanish) diverge for \( \gamma_n < 0 \), \( \gamma_n > 0 \). Using (24), the TBA equations (22) for \( \eta^{(\alpha)}_n \) now read

\[
\alpha \gamma_n = \alpha g_n + \sum_m d\mu a_{nm}(\mu - \lambda) \ln[1 + \exp(-\alpha \gamma_m(\mu))], \tag{25}
\]

In the limit \( \alpha \to \infty \), the last term in (25) in nonzero only for \( \gamma_m < 0 \), and it becomes linear in \( \alpha \). This allows one to rewrite (25) as

\[
\gamma_n = g_n + \sum_m d\mu a_{nm}(\mu - \lambda) \gamma^+_m(\mu), \tag{26}
\]

where we defined \( \gamma^+_m \) as

\[
\gamma^+_m \equiv \begin{cases} 
\gamma_m & \text{if } \gamma_m < 0, \\
0 & \text{if } \gamma_m > 0.
\end{cases} \tag{27}
\]

Notice that, as it is clear from the definition (27), the integrals in (26) are nonlinear. After solving (26), the particle densities \( \rho^{(\infty)}_\alpha \) are obtained by using the TBA equations (5).

One obtains that \( \rho^{(\infty)}_\alpha \) are nonzero only for \( \lambda \) such that \( \gamma_n < 0 \). This happens because the \( \rho^{(\infty)}_\alpha \) cannot diverge, whereas from (24), one has that \( \eta^{(\infty)}_n \) diverge for \( \lambda \) such that \( \gamma_n > 0 \). More quantitatively, in the limit \( \alpha \to \infty \) the system (5) becomes

\[
2\pi \rho_n = a_n - \sum_{m=1}^{\infty} d\mu a_{nm}(\mu - \lambda) \rho_m(\mu) \theta_H(-\gamma_m), \tag{28}
\]

where, again, \( \rho_n \) is nonzero only for \( \lambda \) such that \( \gamma_n < 0 \). The equation for the hole density \( \rho^{(h)}_n \) is given as

\[
2\pi \rho^{(h)}_n = a_n - \sum_{m=1}^{\infty} d\mu a_{nm}(\mu - \lambda) \rho_m(\mu) \theta_H(-\gamma_m), \tag{29}
\]

Notice that (29) is the same as (28), although the support, i.e., the values of \( \lambda \) for which \( \rho_n \) and \( \rho^{(h)}_n \) are nonzero, is different. In fact, the supports of particle and hole densities are complementary. By using (9), it is straightforward to check that this implies that the Yang-Yang entropy is zero. Finally, by taking the limit \( \alpha \to \infty \) in (23), one obtains that

\[
S_{\text{GGE}} = E_{\rho^{(\infty)} + L f_{\text{GGE}}(\rho^{(1)}), \tag{30}
\]

where \( \rho^{(1)} \) is the macrostate describing (quasi) local observables in the steady state. Apart from the contribution of the GGE grand-canonical potential \( f_{\text{GGE}} \), the min entropy is determined by the driving \( E \) only. Also, for quenches that can be treated with the Quench Action, one has \( f_{\text{GGE}} = 0 \), due to the normalization of the overlaps, which further simplifies (30).

### III. OBTAINING THE RÉNYI ENTROPIES IN GHD

Here we discuss the GHD approach to calculate the steady-state Rényi entropies in section III A (see Refs. 165), focusing on the entropies in section III B.

#### A. Generalized Hydrodynamics (GHD)

Let us consider the setup that is depicted in Figure 1. After the quench, information spreads ballistically from the interface between \( A \) and \( B \). At long times, local and quasilocal
quantities depend only on the ratio $\zeta = x/t$, with $t$ the time after the quench and $x$ the distance from the interface between $A$ and $B$. A remarkable result is that in the scaling limit of long times and large distances, for each fixed ray $\zeta$, dynamical properties of the system are described by a GGE. The GGE is identified by a thermodynamic macrostate (see section II B), i.e., by a set of particle and hole densities $\rho_{\zeta,n}$ and $\rho_{\zeta,n}^{(h)}$. For $\zeta = 0$ the macrostate identifies the so-called Non Equilibrium Steady State (NESS). We anticipate that the NESS is the relevant macrostate for describing the steady-state R\'enyi entropies of a subsystem placed at the interface between $A$ and $B$. Clearly, deep in the bulk of the two chains, i.e., for $x/t \to \pm \infty$, the steady state is the same as that arising after the homogeneous quenches with initial states $|\Psi_A\rangle$ and $|\Psi_B\rangle$. Let us denote as $\rho_{\pm \infty,n}$ the macrostates that describe these steady states.

The central result of the Generalized Hydrodynamics is that for generic $\zeta = x/t$, the macrostate $\rho_{\zeta,n}$ satisfies a continuity equation having $\rho_{\pm \infty,n}$ as boundary conditions for $\zeta \to \pm \infty$. The continuity equation is conveniently written in terms of the filling functions $\vartheta_{\zeta,n}$ (cf. (4)) as

$$\left[\zeta - \vartheta_{\zeta,n}(\lambda)\right] \partial_\lambda \vartheta_{\zeta,n}(\lambda) = 0,$$  
(31)

where $\vartheta_{\zeta,n}$ are the group velocities of the low-lying (particle-hole) excitations around $\rho_{\zeta,n}$. Crucially, in (31) there is no explicit scattering term between different quasiparticles. This is a consequence of integrability. Indeed, for interacting integrable models, the full effect of interactions is taken into account by the renormalization of the group velocity $\vartheta_{\zeta,n}$. The TBA calculation of $\vartheta_{\zeta,n}$ will be illustrated below. Notice that in Eq. (31) each ray $\zeta$ can be treated separately. The general solution of (31) can be written as

$$\vartheta_{\zeta,n}(\lambda) = \theta_H(\vartheta_{\zeta,n} - \zeta)(\vartheta_{+ \infty,n} - \vartheta_{- \infty,n}) + \vartheta_{- \infty,n}. $$  
(32)

Here $\theta_H$ is the Heavside theta function and $\vartheta_{+ \infty,n}$ are the boundary conditions in the limits $\zeta \to \pm \infty$. Again, they identify the macrostates describing the steady state after the quenches from $|\Psi_A\rangle$ and $|\Psi_B\rangle$ (see Figure 1), respectively. Notice that the solution (32) is only implicit because the velocities $\vartheta_{\zeta,n}$ have to be determined self consistently. The equations that determine the particle density $\rho_{\zeta,n}$ are the same as in (5). In terms of $\vartheta_{\zeta,n}$ they read as

$$2\pi \rho_{\zeta,n}(1 - \vartheta_{\zeta,n})^{-1} = a_n - \sum_{m=1}^{\infty} a_{nm} * \rho_{\zeta,m}. $$  
(33)

where $\vartheta_{\zeta,n}$ are obtained from (32).

As anticipated, the crucial ingredient of the GHD are the group velocities $\vartheta_{\zeta,n}$. In the Bethe ansatz framework, these are constructed as particle-hole excitations above $\rho_{\zeta,n}$. For generic integrable interacting models the effect of particle-hole excitations is to renormalize (“dress”) the quasiparticle rapidities. This is reflected in a renormalization of the quasi-particle energies and group velocities.

In the following we describe how to calculate this renormalization by using the approach described in Ref. 166. We denote the “dressed” single particle energies by $e_{\zeta,n}$, whereas the “bare” ones are denoted by $e_n$. In terms of $e_{\zeta,n}$, the group velocities $\vartheta_{\zeta,n}$ are written as

$$\vartheta_{\zeta,n} = \frac{e'_{\zeta,n}}{2\pi \rho_{\zeta,n}^{(h)}}. $$  
(34)

Here $e'_{\zeta,n} \equiv de_{\zeta,n}/d\lambda$, and $\rho_{\zeta,n}^{(h)}$ is the total density of the thermodynamic macrostate. The functions $e'_{\zeta,n}$ are obtained by solving the system of nonlinear integral equations

$$e'_{\zeta,n} - e_n' + \frac{1}{2\pi} \sum_m d\mu e'_{\zeta,m}(\mu)a_{nm}(\mu - \lambda)\vartheta_{\zeta,m}(\mu) = 0. $$  
(35)

Here $a_{nm}$ is the same scattering matrix as in the TBA equations (5), and we defined $e_n' \equiv de_n/d\lambda$. A very efficient strategy to solve (31) and (35) is by iteration: One starts with an initial guess for $\vartheta_{\zeta,n}$, using (32) to derive $\vartheta_{\zeta,n}$. Thus, a new set of velocities is determined by using (34) and (35). These two steps are iterated until convergence is reached.

B. GHD approach for R\'enyi entropies

Here we consider a finite subsystem $A'$ of length $\ell$ at the interface between $A$ and $B$ (see Figure 1). We are interested in the steady-state value of the R\'enyi entropy density $S^{(r)}/\ell$ of $A'$ for generic $\alpha$. For $\alpha = 1$ the result has been provided in Ref. 40. The key idea is that for any finite $\ell$, in the limit $t \to \infty$ the density of R\'enyi entropy has to coincide with that of the R\'enyi entropy of the GGE that describes the local equilibrium state. Now, in the limit $t \to \infty$ any finite region around the interface between $A$ and $B$ is described by the GGE with $\zeta = 0$.

The general idea to obtain the steady-state R\'enyi entropies is to combine the GHD framework (see section III A) with the TBA method for the R\'enyi entropies (see section II C). The densities $\vartheta_{\zeta=n,0}$ are obtained by solving the GHD continuity equations (31). Then, the R\'enyi entropies are obtained using the TBA method described in section II. Crucially, the second step requires knowing the driving $g_n$ (see (18) for its definition) that determines $\eta_{n}^{(\alpha)}$. In contrast with homogeneous quenches, $g_n$ is not known a priori. Here, following Ref. 42, $g_n$ is extracted from the TBA equations (18), by substituting the densities $\vartheta_{\zeta=n,0}$ obtained from (31). Finally, $g_n$ is used in the TBA equations (22) and (5) to obtain the densities $\eta_{n}^{(\alpha)}$. The final expression for the R\'enyi entropies densities is given by (23).

IV. ANALYTICAL RESULTS FOR THE XXZ CHAIN

In this section, by using the approach presented in section III, we calculate the steady-state R\'enyi entropies after a quench from a piecewise homogeneous initial state in the XXZ chain. Section IV A introduces the XXZ and the quench protocol, in particular, the expansion quench. The
GHD solution of the expansion quench is detailed in section IV B, IV C, IV D. Finally, in section IV E we present our analytical predictions for the entropies.

A. Model and quench protocols (expansion quench)

The spin-1/2 XXZ chain is defined by the Hamiltonian

$$H = \sum_{i=1}^{L} \left[ \frac{1}{2} \left( S_i^+ S_{i+1}^- + S_i^- S_{i+1}^+ \right) + \Delta S_i^z S_{i+1}^z \right],$$

(36)

where $S_i^+, S_i^-$ are spin-1/2 operators and $\Delta$ is the anisotropy parameter. We consider periodic boundary conditions by identifying sites 1 and $L + 1$ of the chain. We restrict ourselves to $\Delta > 1$. In the generic quench protocol, at $t = 0$ the two chains $A$ and $B$ (see Figure 1) are prepared in two macroscopically different states $\Psi_A$ and $\Psi_B$. At $t > 0$ the unitary dynamics under the XXZ Hamiltonian (36) is investigated. Here we also consider a special type of quench, which we term expansion quench. In the expansion quench part $A$ (see Figure 1) is prepared in the vacuum state of the quasiparticles, which for the expansion quench is equivalent to a box-trap expansion quench (31). First, we restrict ourselves to the case $A$ and $B$ are spin-$\frac{1}{2}$, i.e.,

$$|F\rangle \equiv |\uparrow\uparrow\cdots\rangle.$$  

(37)

After mapping the XXZ chain onto a system of interacting fermions, the expansion quench is equivalent to a box-trap expansion, which is routinely used in cold-atom experiments. Here we only consider the expansion of the Néel state $|N\rangle$ and of the Majumdar-Ghosh (or dimer) state $|MG\rangle$. The Néel state is defined as

$$|N\rangle \equiv \frac{1}{\sqrt{2}} (|\uparrow\uparrow\cdots\rangle + |\downarrow\downarrow\cdots\rangle).$$

(38)

The Majumdar-Ghosh state (dimer state) is defined as

$$|MG\rangle \equiv \frac{1}{2^+} (|\uparrow\downarrow\cdots\rangle - |\downarrow\uparrow\cdots\rangle)(|\uparrow\downarrow\cdots\rangle - |\downarrow\uparrow\cdots\rangle) \cdots.$$  

(39)

B. GHD solution of the expansion quench

It is interesting to discuss the solution of the expansion quench in the XXZ chain by using the framework of the Generalized Hydrodynamics (GHD) (see section III A). Since part $A$ of the system is prepared in the vacuum, a major simplification is that

$$\vartheta_{+\infty,n}(\lambda) = 0, \forall \lambda.$$  

(40)

This has striking consequences in the continuity equation (31). First, we restrict ourselves to the case $\zeta = 0$, which, as already stressed, is the relevant ray to describe the interface between $A$ and $B$ and the steady-state entropies. By using the general solution (32) of (31), Eq. (40) implies that $\vartheta_n$ is written as

$$\vartheta_n(\lambda) = \theta_H(v_n) \vartheta_{-\infty,n},$$

(41)

where we omit the subscript $\zeta$, since we are focusing on $\zeta = 0$. Clearly, from (41), one has that $\vartheta_n(\lambda)$ is non-zero only for $\lambda$ such that $v_n(\lambda) > 0$. An important remark is that from (41) one has that for some rapidities $\lambda$ one has $\vartheta_n(\lambda) = 0$. The physical interpretation is that quasiparticles with these rapidities that are originated in $B$ do not reach the interface with $A$, because their group velocity change sign during the dynamics. It is useful to express Eq. (41) in terms of the dressed energies $e'_n$. By using the definition (34), and the fact that $\rho_n^{(\alpha)}(\lambda) \geq 0$, one has

$$v_n(\lambda) > 0 \Rightarrow e'_n(\lambda) > 0,$$  

(42)

which allows one to replace $\vartheta_H(v_n)$ with $\vartheta_H(e'_n)$ in (41). An important consequence is that the integral equation for the dressed energy $e'_n$ (cf. (35)) is decoupled from the continuity equation (31), and it becomes

$$0 = e'_n - e'_n \vartheta_{-\infty,n}(\lambda)$$

$$- \frac{1}{2\pi} \sum_m d\mu e'_m(\mu) a_{n,m}(\mu - \lambda) \vartheta_{-\infty,n}(\mu) \vartheta_H(e'_m(\mu)).$$

(43)

Here $e'_n$ is the derivative of the bare energy of the quasiparticles and $\vartheta_{-\infty,n}$ is the macrostate describing local equilibrium in the limit $\zeta \to -\infty$.

C. Absence of bound-state transport after the expansion

An intriguing feature of the expansion quench in the XXZ chain is that, for large enough $\Delta$, there is no bound-state transport between $A$ and $B$ (see Figure 1). This is a genuine effect of the interactions, which renormalize (“dress”) the group velocities of the system quasiparticles. Due to this dressing, the group velocities $v_n$ of the bound states with $n > 1$ that are created in $B$ change sign before reaching the boundary with $A$. Formally, the reason for this behavior is that for the XXZ chain in the large $\Delta$ limit one has

$$e'_n < 0, \forall \lambda \ for \ n > 1.$$  

(44)

In the following, we first illustrate the mechanism by which Eq. (44) implies the absence of bound-state transport at large $\Delta$, and then we discuss its regime of validity upon lowering $\Delta$. Eq. (44) implies that in the system of integral equations (43) the equation for $n = 1$ is decoupled from the rest, and it is given as

$$e'_1 = e'_1$$

$$+ \frac{1}{2\pi} \int d\mu e'_1(\mu) a_{1,1}(\mu - \lambda) \vartheta_{-\infty,1}(\mu) \vartheta_H(e'_1(\mu)).$$

(45)

The derivative $e'_n$ of the dressed energy density for bound states with $n > 1$ is obtained by substituting the solution $e'_1$ of (45) in (43). This gives

$$e'_n = e'_n$$

$$- \frac{1}{2\pi} \int d\mu e'_1(\mu) a_{n,1}(\mu - \lambda) \vartheta_{-\infty,1}(\mu) \vartheta_H(e'_1(\mu)).$$

(46)
Eq. (46) has to be used to check (44) self-consistently (see below).

The decoupling of the equation for \( \eta \) in (45) is reflected in a similar behavior for the particle density \( \rho \). From Eq. (5), it is clear that Eq. (44) and (41) imply that \( \eta \to \infty \) and that \( \rho_n \to 0 \) for \( n > 1 \). On the other hand, for \( n = 1 \), one has that \( \rho_1 \) is non-zero only for \( \lambda \) such that \( \epsilon_1' > 0 \). Specifically, from (5) the finite part of \( \rho_1 \) is obtained by solving the integral equation

\[
\rho_1(\vartheta_{-\infty,1})^{-1} - \frac{a_1}{2\pi} = -\frac{1}{2\pi} \int d\mu \alpha_{11}(\lambda - \mu)\rho_1(\mu)\vartheta_H(\epsilon_1'(\mu)).
\]

The fact that \( \rho_n \) is identically zero for \( n > 1 \) implies that the bound states with \( n > 1 \) do not affect the local equilibrium properties at the interface between \( A \) and \( B \). Equivalently, the information about the bound states that are created in \( B \) does not arrive at the interface with \( A \).

We now discuss the validity of this result as a function of \( \Delta \). The strategy is to check (44) by substituting the solution of (45) in (46). This gives the condition

\[
\epsilon_n' = \frac{2}{\pi} \int d\mu \epsilon_1'(\mu)\alpha_{11}(\lambda - \mu)\vartheta_{-\infty,1}(\mu)\vartheta_H(\epsilon_1'(\mu)) < 0.
\]

We now show that for the expansion quench the condition (48) is satisfied in the XXZ chain with large enough \( \Delta \). First, one can verify that the leading order of the bare energy \( \epsilon_n' \) for large \( \Delta \) is given as

\[
\epsilon_n' = \frac{2}{\pi} = 2\sin(2\lambda) + O(z^{n+1}), \quad \text{with } z \equiv e^{-\eta}.
\]

We now assume that \( \epsilon_1' = O(1) > 0 \) for some rapidities \( \lambda \). We also assume that \( \vartheta_{-\infty,1} > 0 \) and \( \vartheta_{-\infty,1} = O(1) \). These conditions are verified for all the quenches considered in this work. It is also natural to expect that they hold true for a larger class of quenches. Now, using that in the large \( \Delta \) limit, \( \alpha_{11} = O(1) \) and \( \alpha_{11} > 0 \), one has that the second term in (48) is \( O(1) \) and negative, whereas the first one can be made arbitrarily small upon increasing \( \Delta \) (cf. (49)). This allows us to conclude that Eq. (44) holds true for large enough \( \Delta \). Upon lowering \( \Delta \), at a certain value \( \Delta^*_n \) the \( n \)-particle bound states start to be transmitted between the two chains. These “critical” \( \Delta^*_n \) depend on the initial state that is released. Furthermore, we observe that, at least for the first few values of \( n \), \( \Delta^*_n < \Delta_n^* \) for \( n > m \), i.e., larger bound states start to be transmitted at smaller \( \Delta \). Finally, for the initial states that we consider (Néel state and Majumdar-Ghosh state) we notice that \( \Delta^*_1 < 1.5 \).

D. Expansion quench in the large \( \Delta \) limit: Exact results

Before discussing the steady-state entropies, it is useful to investigate the large \( \Delta \) expansion of the macrostate describing local and quasilocal observables. Here we focus on the expansion of the Néel state and the Majumdar-Ghosh state.

1. Expanding the Néel state

By using (41) and the fact that for the Néel state in the limit \( \Delta \to \infty \) one has that \( \vartheta_{-\infty,1} \to 1 \), one obtains that \( \vartheta_1 \) becomes a step function. Precisely, one has

\[
\vartheta_1 = \vartheta_H(\epsilon_1'(\lambda)).
\]

Equation (49) and the fact that \( a_1 = 2 \) at the leading order in \( 1/\Delta \) imply that the dressed energy \( \epsilon_1' \) is obtained by solving the integral equation (cf. (43))

\[
\epsilon_1' = 2\sin(2\lambda) - \frac{1}{\pi} \int d\mu \epsilon_1'(\mu)\vartheta_H(\epsilon_1'(\mu)).
\]

Eq. (51) implies that

\[
\epsilon_1' = 2\sin(2\lambda) + \gamma,
\]

with \( \gamma \) to be determined. After substituting (52) in (51) one obtains an equation for \( \gamma \) as

\[
2\sin(2\lambda) + \gamma = 2\sin(2\lambda) - \frac{1}{\pi} \int d\mu (2\sin(2\lambda) + \gamma),
\]

where we defined

\[
\lambda_- = \frac{1}{2} \arcsin\left(\frac{\gamma}{2}\right),
\]

\[
\lambda_+ = \frac{\pi}{2} + \frac{1}{2} \arcsin\left(\frac{\gamma}{2}\right).
\]

By performing the integral in (53), one obtains that \( \gamma \) is the solution of

\[
\frac{1}{\pi} \left[\sqrt{4 - \gamma^2} + \gamma \arccos\left(\frac{\gamma}{2}\right)\right] = 0.
\]

Eq. (56) cannot be solved analytically. From (56) one obtains numerically \( \gamma \approx -0.3989 \).

We now determine the particle density \( \rho_1 \). First, by using the TBA equation (47) together with (50), one has that \( \rho_1 \) is zero for \( \lambda \notin [\lambda_-, \lambda_+] \). For \( \lambda \in [\lambda_-, \lambda_+] \), \( \rho_1 \) is obtained by solving

\[
\rho_1 - \frac{1}{\pi} + \frac{1}{\pi} \int d\mu \rho_1 = 0,
\]

where we used the TBA equation (47), and that at the leading order in \( 1/\Delta \) one has \( a_1 = 2 \). From (57), one has that \( \rho_1 \) exhibits a Fermi-sea structure, and it is given as

\[
\rho_1 = \begin{cases} 
\left[\pi + \lambda_+ - \lambda_-\right]^{-1} & \text{if } \lambda \in [\lambda_-, \lambda_+] \\
0 & \text{otherwise}
\end{cases}
\]

(58)

On the other hand, the hole density \( \rho^h_1 \) is nonzero only for \( \lambda \notin [\lambda_-, \lambda_+] \), where \( \rho^h_1 = \left[\pi + \lambda_+ - \lambda_-\right]^{-1} \). The fact that the hole and the particle density have complementary support implies that in the limit \( \Delta \to \infty \) the Yang-Yang entropy is vanishing.
2. Expanding the Majumdar-Ghosh state

A similar expansion can be obtained for the expansion of the Majumdar-Ghosh state. In contrast with the Néel state (see section IV D 1), at the leading order in $1/\Delta$ one now has $\vartheta_{-\infty,1} = \cos^2(\lambda)$. The leading order in $1/\Delta$ of the dressed energy $e'_1$ (cf. (45)) is now obtained by solving

$$e'_1 = 2\sin(2\lambda) - \frac{1}{4} \int d\mu e'_1(\mu) \cos^2(\mu) \vartheta_H(e'_1(\mu)).$$  \hspace{1cm} (59)

Eq. (59) implies that

$$e'_1 = 2\sin(2\lambda) + \gamma',$$  \hspace{1cm} (60)

where $\gamma'$ is obtained by solving

$$\frac{1}{2\pi} \left[ 4 - \gamma'^2 + \gamma' \arccos\left(\frac{\gamma'}{2}\right) \right] + \gamma' = 0.$$ \hspace{1cm} (61)

Eq. (61) gives $\gamma' \approx -0.2487$. Eq. (61) is the same as (56), apart from a factor $1/2$ in the first term. The TBA equation (47) for the particle density $\rho_1$ is

$$\frac{\rho_1}{\cos^2(\lambda)} - \frac{1}{4} + \frac{1}{4} \int d\mu \rho_1(\mu) \vartheta_H(e'_1(\mu)) = 0.$$ \hspace{1cm} (62)

This implies that $\rho_1 = \gamma'' \cos^2(\lambda)$. From (62) the constant $\gamma''$ is obtained as

$$\gamma'' = \left[\frac{5}{4} - \frac{\arcsin\left(\frac{\gamma'}{2}\right)}{2}\right]^{-1},$$ \hspace{1cm} (63)

where $\gamma'$ is the solution of (61). Finally, the result for $\rho_1$ is written as

$$\rho_1 = \begin{cases} 
\cos^2(\lambda) \left[\frac{\pi}{2} - \lambda_+ + \lambda_-\right]^{-1} & \text{if } \lambda \in [\lambda_-', \lambda_+'] \\
0 & \text{otherwise}
\end{cases} \hspace{1cm} (64)
$$

where we defined

$$\lambda_-' = -\frac{1}{2} \arcsin\left(\frac{\gamma'}{2}\right),$$ \hspace{1cm} (65)

$$\lambda_+ = \frac{\pi}{2} + \frac{1}{2} \arcsin\left(\frac{\gamma'}{2}\right).$$ \hspace{1cm} (66)

Notice that $\lambda_\pm'$ coincide with $\lambda_\pm$ (cf. (54)-(55)) after the substitution $\gamma' \to \gamma$. Clearly, in contrast with the Néel state (see section IV D 1), $\rho_1$ is not a step function.

E. Rényi entropies after the expansion quench

We now calculate the steady-state entropies after the expansion quench. We restrict ourselves to $\Delta > \Delta^*_2$ (see section IV C), which allows us to neglect the contribution of the multispin bound states with $n > 1$.

As described in section III B, the first step is to determine the driving functions $g_n$ (see Eq. (18) and Eq. (22)). Here $g_n$ is obtained by first solving (43) for $e'_n'$ and then by substituting in

$$g_n = \ln(\vartheta_{-\infty,n}(\vartheta_H(e'_n'))^{-1} - 1)$$

$$+ \sum_m \int d\mu \varrho_{nm}(\mu - \lambda) \ln(1 - \vartheta_{-\infty,m}(\vartheta_H(e'_m'))).$$ \hspace{1cm} (67)

where we used that for the expansion quench $\vartheta_n = \vartheta_H(e'_n') \vartheta_{-\infty,n}$.

By using that $e'_n < 0$ for $n > 1$, one obtains that $g_n$ is divergent for any $\lambda$ for $n > 1$, whereas $g_1$ diverges for $\lambda$ such that $e'_1 < 0$, and it is finite otherwise. To derive the Rényi entropies one has now to solve the TBA equations with the modified driving $\alpha g_n$. As a consequence of the results outlined above, some simplifications occur. Let us consider the integral equations (22) for $\eta_n^{(\alpha)}$

$$\ln(\eta_n^{(\alpha)}) = \alpha g_n$$

$$+ \sum_{m=1}^{\infty} \int d\mu \varrho_{nm}(\mu - \lambda) \ln(1 + 1/\eta_m^{(\alpha)}(\mu)).$$ \hspace{1cm} (68)

First, in Eq. (68), the integral in the right hand side is nonzero only if $\eta_m^{(\alpha)}$ is finite. Thus, from (68), one has that $\eta_n = \alpha g_n$ are divergent for $m > 1$ because $g_n$ are divergent. On the other hand, $\eta_1$ is divergent for $\lambda$ such that $g_1$ is divergent. This implies that the equation for $\eta_1^{(\alpha)}$ is decoupled from the rest and it is given as

$$\ln(\eta_1^{(\alpha)}) = \alpha g_1 \vartheta_H(e'_1)$$

$$+ \int d\mu \varrho_{11}(\mu - \lambda) \ln(1 + 1/\eta_1^{(\alpha)}(\mu)) \vartheta_H(e'_1)).$$ \hspace{1cm} (69)

Here $e'_1$ is obtained by solving (45). We now discuss the macrostate densities $\rho_1^{(\alpha)}$. The TBA equations (5) become

$$2\pi \rho_1^{(\alpha)}(1 + \eta_1^{(\alpha)}) = a_n - \sum_m \int d\mu \varrho_{nm}(\mu - \lambda) \rho_1^{(\alpha)}(\mu).$$ \hspace{1cm} (70)

Clearly, $\rho_1^{(\alpha)}$ is zero for $n > 1$, reflecting the divergent behavior of $\eta_m^{(\alpha)}$. Also, $\rho_1^{(\alpha)}$ is non-zero only for $\lambda$ such that $\eta_1^{(\alpha)}$ is finite. To obtain the finite part of $\rho_1^{(\alpha)}$ one has to solve the integral equation

$$2\pi \rho_1^{(\alpha)}(1 + \eta_1^{(\alpha)}) = a_1 - \int d\mu \varrho_{11}(\mu - \lambda) \rho_1^{(\alpha)}(\mu) \vartheta_H(e'_1).$$ \hspace{1cm} (71)

It is interesting to observe that for any finite $\alpha$ the support of $\rho_1^{(\alpha)}$ does not depend on $\alpha$, but it is determined by the condition $e'_1 > 0$.

It is now worth making some remarks on the treatment of the single copy entanglement for $\alpha \to \infty$. Similar to finite $\alpha$, one has to determine the TBA density $\eta_1^{(\infty)}$. The ansatz (24) becomes

$$\eta_1^{(\alpha)} = \exp(\alpha \gamma_1),$$ \hspace{1cm} (72)

where the function $\gamma_1$ has to be determined. One has that in
the limit $\alpha \to \infty$, Eq. (26) becomes

$$\gamma_1 = g_1 - \int d\mu \rho_1(\mu - \lambda) \gamma_1^+(\mu),$$  \hspace{1cm} (73)

where $\gamma_1^+$ is defined in (27). The particle density $\rho_1^{(\infty)}$ (cf. (28)) becomes

$$2\pi \rho_1^{(\infty)} = a_1 - \int d\mu \rho_1(\mu - \lambda) \rho_2(\mu) \theta(-\gamma_1).$$  \hspace{1cm} (74)

The nonzero part of $\rho_1^{(h,\infty)}$ is obtained by using (29). An interesting observation is that, while for finite $\alpha$ the support of $\rho_1^{(\infty)}(\lambda)$, i.e., the values of $\lambda$ for which $\rho_1^{(\infty)}$ is nonzero, is determined by the condition $\epsilon_1^*(\lambda) > 0$, and it is the same for any $\alpha$, this, in principle, is not the case in the limit $\alpha \to \infty$. In that limit, one has that the support of $\rho_1^{(\infty)}(\lambda)$ is determined by the condition $\gamma_1(\lambda) < 0$, with $\gamma_1$ solution of (73). In general one has that $\{\lambda | \gamma_1(\lambda) < 0\} \subset \{\lambda | \epsilon_1^*(\lambda) > 0\}$.

F. Numerical TBA results

We now provide exact numerical results for the steady-state entropies after the quench from a piecewise homogeneous initial state in the XXZ chain.

1. Macrostate densities and “critical” anisotropies

Numerical results for the macrostate densities $\vartheta_n^{(\alpha)}$ and $\rho_n^{(\alpha)}$ are shown in Figure 2, for the expansion quenches of the Néel state and of the Majumdar-Ghosh state (first and second column, respectively), and for the quench from $|N \otimes MG\rangle$ (third column in Figure 2). For the expansion quenches we restrict ourselves to $\Delta > \Delta_\ast$ (see section IV C for its definition). As it has been already discussed, this implies that only the densities $\vartheta_n^{(\alpha)}$ and $\rho_n^{(\alpha)}$ are nonzero. For $|N \otimes MG\rangle$ we show only results for $n = 1$, although all the densities with $n > 1$ are nonzero. Also, one should observe that for the expansion quenches the densities are nonzero only in a subset of $[-\pi/2, \pi/2]$, whereas for $|N \otimes MG\rangle$ they are nonzero in the full interval $[-\pi/2, \pi/2]$. Finally, as it is clear from panel (c), $\vartheta_1$ exhibits a quite weak dependence on $\alpha$.

It is interesting to extract the “critical” anisotropies $\Delta_\ast^\pm$ for the expansion quenches. Here we focus on $\Delta_+$. As we discussed in section IV C, for $\Delta > \Delta_+^\pm$ one has that $\epsilon_2^* < 0$, giving $\vartheta_2^{(\alpha)} = 0$, which implies that transport of the two-particle bound states between $A$ and $B$ is absent. Formally, $\Delta_\ast^+$ is the point at which $\epsilon_2^*$ becomes positive. This is discussed in Figure 3 showing $\epsilon_2^*$ as a function of $\lambda$, for the expansion of the Néel state and the Majumdar-Ghosh state. For the Néel state (panel (a)), one has that for any $\lambda$, $\epsilon_2^* < 0$ for $\Delta > 1.4$, whereas $\epsilon_2^* > 0$ for $\Delta = 1.3$, which suggests that $1.3 \gtrsim \Delta_\ast^+ \gtrsim 1.4$. For the Majumdar-Ghosh state one has a much smaller values for $\Delta_\ast^+$. Indeed, from panel (b) it is clear that $\Delta_\ast^+ < 1.1$. The same analysis could be performed for the three-particle bound states, i.e., for $n = 3$. One should expect a new “critical” anisotropy $\Delta_\ast^3 \leq \Delta_\ast^2$. For $\Delta < \Delta_\ast^1$ transport of the two-particle and three-particle bound states is permitted. We numerically observed that $\epsilon_3 \ll \epsilon_2$ for $\Delta < \Delta_\ast^2$, suggesting that there is an extended region in $\Delta$ where only transport of 2-particle and 3-particle bound states is allowed. It is natural to expect that a similar scenario occurs for larger bound states, i.e., that there is a “cascade” of transition points $\Delta_\ast^1 > \Delta_\ast^2 > \Delta_\ast^3 > \Delta_\ast^4 \ldots$ This would lead to the intriguing scenario in which transport of larger and larger bound states is activated at smaller and smaller anisotropies.

Finally, it is useful to consider the limit $\alpha \to \infty$. We focus on the quench from $|N \otimes MG\rangle$. Figure 4 shows the TBA
The densities reported in Figure 2 are used to calculate the steady-state entropies by using (23). Figure 5 shows the contributions of the individual quasiparticles to the entropies, plotted versus λ. We report results for the expansion of the Néel state and the Majumdar-Ghosh state (in (a) and (b)). Data for the quench from $|N \otimes MG\rangle$ and for $n = 1$ and $n = 2$ are shown in (c) and (d). Notice, however, that for $|MG \otimes N\rangle$, bound states with $n > 1$ contribute to the Rényi entropies, although we do not report them in the figure. Data in panel (a) and (b) are for the XXZ chain with $\Delta = 2$, while in (c) and (d) we consider $\Delta = 5$. While the entropy density for the expansion quench is positive for all values of λ (see panels (a) and (b)), this is not the case for $|N \otimes MG\rangle$. The same behavior, i.e., that the density of Rényi entropies is not positive, was observed in homogeneous quenches, and it is the main obstacle when applying the quasiparticle picture to describe the full-time dynamics of the entropies. The GHD prediction for the steady-state entropies is obtained by integrating the results in Figure 5 and by summing over the quasiparticle families. The results are reported in Figure 6 as a function of $\Delta$, and for different initial states. For all the quenches one has that $S^{(n)} < S^{(1)}$, for $\alpha' < \alpha$, as expected. For the expansion of the Néel state, all the Rényi entropies vanish in the large $\Delta$ limit. This reflects that the Néel state is the ground state of the XXZ chain in that limit, similar to the homogeneous case. For the expansion of the Majumdar-Ghosh state the entropies exhibit a quite weak dependence on $\Delta$. Results for the quench from $|N \otimes MG\rangle$ are reported in panel (c). The entropy densities exhibit a decreasing trend upon increasing $\Delta$, although they do not vanish in the limit $\Delta \to \infty$.

V. DMRG RESULTS FOR THE XXZ CHAIN

We now turn to compare the TBA results presented in section IV against tDMRG simulations. We restrict ourselves to the expansion quenches of the Néel and the Majumdar-Ghosh states, as they are easier to simulate with tDMRG. We employ the framework of the Matrix Product States (MPS). All the considered initial states admit a simple MPS representation with rather small bond dimension $\chi$. The initial states are time-evolved by using a standard second order Trotter-Suzuki decomposition of the evolution operator $e^{-iHt}$. The Trotter time discretization step is $\delta t = 0.05$. At each step of the evolution the state looses its MPS form, which has to be restored by performing a singular value decomposition (SVD). To prevent the rapid growth of $\chi$, a truncated SVD is performed with maximum allowed bond dimension $\chi_{\text{max}}$. In our simulations we employed $\chi_{\text{max}} = 80$. Importantly, here we are interested in calculating the Rényi entropies of a subsystem embedded in the chain (see Figure 1). In the standard MPS framework, the computational cost for calculating the entropy is $\propto \chi^0$ (see Ref. 168 for the details), in contrast with the cost for calculating the half-chain entropy, which is only $\propto \chi^3$.

Our tDMRG data are reported in Figure 7 for both the Néel state and of the Majumdar-Ghosh state. The Figure shows the entropy density $S^{(n)}/\ell$ versus time. All the results are for the XXZ chain with $L = 40$. Different curves correspond to different values of $\ell$. For clarity, we only show results for odd $\ell$. Panels (a-d) show data for the Néel state and for $\alpha = 2$ and different values of $\Delta$. Panels (e-h) show the results for the Majumdar-Ghosh state. Specifically, panels (e-f) plot $S^{(n)}/\ell$ for $\Delta = 2$ and $\Delta = 4$, whereas panels (g-h) are for $S^{(n)}/\ell$ for the same values of $\Delta$. For the Néel state, the entropy density decreases upon increasing $\Delta$, as expected in the scaling limit (see Figure 6). Interestingly, sizeable oscillations with time are observed, whose amplitude increases with increasing $\Delta$. This is similar to the homogeneous quench from the Néel state. On the other hand, for the Majumdar-Ghosh state, although oscillations with time are present, they decay quite rapidly with increasing $\ell$, and their amplitude does not increase upon increasing $\Delta$. The comparison between the Bethe ansatz results for the Rényi entropies is presented in Figure 5. Panels (a)-(d) show $S^{(n)}/\ell$ for $\alpha = 2, 3$. In all the panels the different symbols are tDMRG data for different values of $\Delta \in [2, 10]$ and $\ell \leq 10$. On the $x$-axis we show $1/\ell$. The raw
tDMRG data are reported in Figure 7. The results presented in Figure 5 are obtained by averaging the tDMRG results for $t > 10$, to mitigate the effect of the oscillations with time. The star symbols are the TBA results in the scaling limit (see Figure 6). Clearly, due to the finite $\ell$, corrections are visible. To recover the scaling limit results, we perform a finite-size scaling analysis. The dashed-dotted lines in Figure 5 are fits to

$$S^{(\alpha)} = \left[ s_\infty^{(\alpha)} + \frac{a}{\ell} + \frac{b}{\ell^2} \right] \ell,$$

where $s_\infty^{(\alpha)}$ is the TBA prediction and $a, b$ are fitting parameters. In all the panels the fits confirm that in the scaling limit the steady-state Rényi entropies are described by the TBA results.

VI. CONCLUSIONS

We investigated the steady-state Rényi entropies after a quench from a piecewise homogeneous initial state in interacting integrable models. Our results were obtained by combining the TBA approach for the Rényi entropies developed in Ref. 40 and the GHD treatment of the quench. We provided explicit results for quenches in the anisotropic Heisenberg XXZ chain from several initial states. We benchmarked our results against tDMRG simulations, finding always satisfactory agreement. We also investigated the steady-state entropies after the expansion quench, in which one of the two chains is prepared in the vacuum of the model excitations. Interestingly, we observed that for large enough anisotropy the transport of multi-spin bound states is not allowed. This is reflected in the steady-state entropies, which do not contain information about the bound states. On the other hand, we showed that there is a “critical” anisotropy below which bound-state transport is allowed.

We now discuss some open problems and possible directions for future work. First, it is important to extend the quasiparticle picture to describe the full-time dynamics of the Rényi entropies after the quench. To this purpose, two main issues appear. First, similar to the von Neumann entropy, describing the full-time dynamics of the Rényi entropies requires determining the trajectories of the quasiparticles as function of time, which implies that rays with $\zeta \neq 0$ have to be considered. This analysis has been performed in Ref. 169 for the von Neumann entropy. A more severe obstacle is that the TBA macrostate that describes the steady-state entropies is not the same as that describing (quasi)local observables and the von Neumann entropy, similar to what happens for homogeneous quenches. This does not provide the correct framework for describing the entropy dynamics, because the excitations that are responsible of the entanglement growth are the ones constructed around the steady state. To apply the quasiparticle description to the Rényi entropies one would first need to express the entropy densities as function of the TBA macrostate that describes the steady state. This, however, is still an open problem.
and difficult problem.

It would be also important to extend our analysis to different initial states, such as the tilted Néel state and the tilted ferromagnet. For the latter case, it would be interesting to investigate the effect of the tilting on the bound-state transport between the two chains. Another interesting direction is to consider piecewise homogeneous quenches in continuum systems such as the Lieb-Liniger model, or in the Hubbard chain in the limit of strong interactions.

VII. ACKNOWLEDGEMENTS

I acknowledge very fruitful discussions with Benjamin Doyon. I am grateful to Maurizio Fagotti and Bruno Bertini for several discussions on a related project. I thank Pasquale Calabrese for reading the manuscript and for several comments. This work was supported by the European Union’s Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 702612 OEMBS.
