Abstract. We present multi-color photometry and time resolved spectroscopy of OU Vir. The analysis of the quiescent light curve shows that OU Vir is characterized by i) strong cycle-to-cycle brightness variations, and ii) hot spot modulated light curve with grazing eclipse of the impact region. Colors are derived both in- and out-of-eclipse. The time-resolved spectroscopy allows us to produce the radial velocity curve from the Hα accretion disk emission line which possibly reveals only weak evidence for hot spot line emission. The hot spot is believed to be a turbulent optically thick region, producing mostly continuum emission.

Key words. dwarf novae – multi-color photometry – time resolved spectroscopy – OU Vir

1. Introduction

The object LBQS 1432-0033 (alias Vir 4 in Downes et al. 1997 catalog, OU Vir in Downes et al. 2001 catalog) was discovered by Berg et al. (1992) as part of their quasi-stellar object spectroscopic survey. Downes et al. (1997) list the object as a cataclysmic variable (CV) of unknown type with Bpg=18.5 based on the Berg et al. spectrum. Vanmunster et al. (2000) present a photometric review for the object indicating that OU Vir is an eclipsing CV with a period of 1.75 hr and has been seen in outburst and probably in superoutburst. These authors quote an outburst amplitude of near 4 magnitudes with a probable inter-outburst period near 79 days. The only other published spectrum of OU Vir is in Szkody et al. (2002).

The spectra by Berg et al. (1992) and Szkody et al. (2002), are characterized by strong double peaked emission lines from the accretion disk. Eclipses and double peaked lines are both signatures of high orbital inclination systems. High orbital inclination systems are preferred targets for the understanding of the binary system geometry and the accretion process, due to the large amount of information provided by both their light curve and time resolved spectroscopy.

Here, we present new photometric and spectroscopic observations for OU Vir. Our multi-color photometry reveals the stars behavior in the B through I bands. Our time-resolved spectroscopic observations of OU Vir have been used to produce the first radial velocity curve for this object, as well as to study the spectrum throughout the orbit. We discuss the data collection and reduction in Sect. 2, our analysis in Sect. 3, and a discussion of our results in Sect. 4.

2. Observations

2.1. Multi-color Photometry

Time resolved multi-color photometry of OU Vir was obtained using the New Mexico State University 1 m telescope located at Apache Point Observatory. OU Vir was observed over eight nights between 2001 April 13 and May 1 using an Apogee 512x512 thinned back-side illuminated CCD with standard Johnson/Cousins BVRI filters. On each of the nights, one entire orbital period was covered

Send offprint requests to: E. Mason

http://loki.apo.nmsu.edu/~tcomm/index.html
by cycling through the four filters. Exposure times were three minutes in B, and two minutes in V, R, and I. To increase the precision of the timing of the photometric eclipse, OU Vir was observed for a complete cycle on May 1 using only the V-band filter. The log of the photometric observations can be found in Table 1.

Data reduction was carried out according to standard routines, and aperture photometry was performed on OU Vir and four other nearby field stars in order to obtain differential magnitudes (e.g. Howell et al. 1988). On 2001 June 6, these field stars were calibrated to the system of Landolt by observations of the standard stars SA102-58, SA102-620, SA105-66, SA106-485, SA107-544.

2.2. Spectroscopic Observations

OU Vir was observed using the red channel spectrograph at the MMT Observatory on the night of 29 March 2001 UT. A single 900 sec blue (4000-5250Å) spectrum was obtained along with a time-series of 600 sec red (5600-8500Å) exposures. Table 2 gives a log of the observations. The setup used a 1 arcsec slit giving spectral resolutions of 0.5 Å/pixel in the blue and 1.0 Å/pixel in the red. The night appeared to be photometric and had constant seeing (∼1.2 arcsec), as evidenced by examination of the slit viewer monitor. Brightness changes of OU Vir were also quite obvious in the slit viewer monitor. The data were reduced in IRAF using average bias and red/blue flat fields taken at the start of the night. HeNeAr arc lamp exposures were obtained at each standard star position before and after every three OU Vir observations. The standard star HZ 44, used to flux calibrate another standard system of Landolt by observations of the standard stars SA102-58, SA102-620, SA105-66, SA106-485, SA107-544.

Table 2. Log of observation of the spectroscopic run. Due to the time in the headers being inconsistent with respect to the telescope console time, we have recorded the latter one in this table. It is recorded only to the minute.

| UT Start-Exposure | Wavelength | Integration Time (sec) |

3. Data Analysis

Upon phasing our photometric and spectroscopic data we encountered the problem of choosing an appropriate ephemeris. Vanmunster et al. (2000) determined the OU Vir orbital period and ephemeris by fitting six eclipses during the June 2000 outburst. Phasing of our photometric data according their ephemeris produced light curves showing eclipse minima at phase ~0.8. The phase offset between our and Vanmunster et al. (2000) eclipse minima is easily explained by the error propagation of the uncertainties in their ephemeris. On the other hand, the time resolution of both our photometric and spectroscopic data is not high enough to produce accurate ephemeris. We thus, decided to phase all our data using the orbital period determined by Vanmunster et al. (2000) but we used the time $T_0$ corresponding to the eclipse minimum of our May 1st V band light curve (which however still has a time resolution of only 2-3 min).

3.1. Photometry

We have plotted the multi-color light curves of OU Vir in Fig. 1. In Fig. 1, each single night is plotted using a different symbol in order to show the strong intrinsic brightness variations of OU Vir. Despite the night by night brightness variations we analyzed each waveband light curve using all data points at a time, as single night light curves have too few points.

Averaging the points in each light curve (excluding the eclipse) we find the following mean colors: $V = 18.08$, $B - V = 0.14$, $V - R = 0.95$, and $V - I = 0.68$. Rough eclipse colors have been computed averaging the two faintest data points in the run for each waveband. We found $V_e=19.17$, $B-V_e=0.24$, $V-R_e=1.05$ and $V-I_e=0.87$. Eclipse colors are redder than out of eclipse, possibly providing evidence of secondary star contribution.

Common features to each light curve are the deep eclipse and a pre-eclipse hump. The eclipse is about 1 mag deep and shows asymmetric ingress and egress profiles (the ingress being steeper than the egress), in each waveband. The pre-eclipse hump varies in amplitude depending on the photometric waveband. The pre-eclipse hump is particularly evident in the B and V bands (~0.3 mag and 0.22 mag, respectively), and decreases in amplitude at longer wavelengths. A closer inspection of the B

\footnote{We searched our radial velocity measurements for periodicity by using the PDM routine (Stellingwerf 1978) finding an orbital period of ~102 min, in quite good agreement with the photometric observation by Vanmunster et al. (2000). However, the resulting uncertainties on the orbital period was of ~20 min due to the relatively low number of spectra in hand.}
and V light curves shows a weak secondary maximum near phase $\sim 0.3$ and/or a secondary minimum at phase $\sim 0.6$.

In Table 3, we list the average magnitude for each of the above mentioned features in each light curve. We believe that the light curve shape is due to the hot spot which is seen from the outside around orbital phase 0.9 (the pre-eclipse hump) and from the inside around phase $\sim 0.4$.

Similar double humped light curves have been observed in the high inclination, short orbital period systems WZ Sge (Skidmore 1998), OY Car (Schoembs & Hartmann 1983), Z Cha (Wood et al. 1986, van Amerongen et al. 1990), and DV UMa (Howell et al. 1988). Causes for these types of modulations are either optically thin accretion disks with an anisotropically emitting hot spot, or an optically thick accretion disk which partially eclipses the hot spot when viewed from the inside.

Average BVRI magnitudes and colors were also computed for each single night\footnote{In this case, no eclipse points were ruled out due to the poor time resolution which does not allow us to properly distinguish the features in each light curve.}. Plots of the night average magnitude vs. time showed that the intrinsic brightness variations are random and with no trend and/or long term variations. The colors vary by $\sim 0.1$ mag and these small variations are not correlated with the magnitude.

### Table 4. Continuum and line flux values as measured in the Blue spectrum and the average red spectrum.

| Line (Å) | Flux (erg cm$^{-2}$ sec$^{-1}$ Å$^{-1}$) | Continuum (erg cm$^{-2}$ sec$^{-1}$ Å$^{-1}$) | Spectrum |
|----------|---------------------------------|---------------------------------|----------|
| 4101.7   | 1.60E-14                        | 8.99E-16                        | Blue     |
| 4340.5   | 2.07E-14                        | 7.59E-16                        | Blue     |
| 4471.6   | 4.82E-15                        | 6.84E-16                        | Blue     |
| 4861.3   | 2.44E-14                        | 5.75E-16                        | Blue     |
| 6562.8   | 5.86E-14                        | 8.24E-16                        | Red      |
| 7065.2   | 3.81E-15                        | 7.94E-16                        | Red      |

### 3.2. Spectroscopy

The OU Vir Red spectra show the emission lines Hα and HeI 5876, 6678, and 7065, while the Blue spectrum shows the Balmer lines Hδ, Hγ, and Hβ, the HeI lines 4471 and 5016, the Fe II lines 5018 (blending with He I 5016) and 5169, and the HeII line 4686 (Fig. 2). Line flux measurements (for the strongest lines) are listed in Table 4.
The red spectra are time resolved, thus, radial velocity measurements of the Hα emission line were obtained. We made use of two different methods to measure the Hα emission line radial velocity: i) the double Gaussian fit method (Shafter 1983, Schneider & Young 1980), and ii) the line flux barycenter. The best fitting sinusoidal curves for the two cases are in Table 5 and Fig. 3. The two methods provides best fit sinusoidal curves which agree within the uncertainties. Measures of the line flux barycenter are expected by definition to be biased by the hot spot emission which breaks the symmetry of the accretion disk emission line. The double Gaussian fit method, when fitting the wings of the accretion disk emission lines is assumed to be free hot spot bias. Thus, the fact that the two sinusoidal curves are statistically identical possibly implies that there is no a significant hot spot contribution in the emission lines biasing the radial velocity measurements. However, it must be noted that the derived spectroscopic inferior conjunction is considerably offset with respect to the photometric phase zero (with an offset of ~0.28, which is much larger than the uncertainty on the real eclipse minimum time in our photometric light curve). Similar phase offsets are common in other dwarf novae (see Mason et al. 2000, and references therein). Though phase offsets are expected to be large in WZ Sge type objects (Mason et al. 2000), there is evidence for large phase offset also in systems which do not show strong hot spot contribution (e.g. Mason et al. 2001). However, OU Vir phase offset appears exceptionally large, the typical values in the literature being in the range 0.02-0.2, in dwarf nova systems (Mason et al. 2000). To further investigate the hot spot fractional contribution to the OU Vir red light we made an Hα trailed spectrum and back projected Doppler map (Figs. 4 and 5, respectively).

The trailed spectrum in Fig. 4 shows only marginal evidence for a S-wave component. Fig. 4 also shows that the S-wave component is possibly asymmetric moving faster from the red-to-blue than from the blue-to-red accretion disk emission peak. The times of the maximum red and blue shifts of the S-wave are not 0.5 phase apart, but occur at phases 0.22 and 0.60, respectively. Similarly, the red to blue crossing and the blue to red crossing of the S-wave seem to occur at phases 0.02 and 0.45, respectively.
The back projected Doppler map (Fig. 5) shows a quite uniform accretion disk with a stronger emission (∼30% stronger than the accretion disk), roughly at the secondary star position \((v_X \sim -125\, \text{km\,sec}^{-1}, v_Y \sim 600\, \text{km\,sec}^{-1})\). Interpretations of both the S-wave in Fig. 4 and the bright spot in Fig. 5 are not obvious. If real, the asymmetry of the S-wave component pointed out above, excludes it is originating from a source in circular Keplerian motion such as the secondary star. Moreover, the bright spot in the Doppler map, if interpreted as secondary star emission, implies irradiation by the hot spot (which is not emitting in the lines), rather than the white dwarf. We must not forget that the spectra are phased according to our May 1st \(V\) band light curve and that there is a large real offset between the spectroscopic and the photometric time for the secondary star inferior conjunction. Phasing of the spectra according to the derived time of the red to blue crossing would rotate counterclockwise the Doppler map by ∼103° and place the bright emission closer to the expected hot spot position.

A straightforward conclusion is that the accretion disk emission lines are not good tracers of the primary star Keplerian motion (no matter if the hot spot is present or not!), and that the radial velocity measurements do not correspond to the white dwarf orbital motion.

4. Discussion and Conclusions

We have observed asymmetric eclipses in all four optical band-passes for the high orbital inclination system OU Vir. Comparison of the eclipse shape and depth with that observed in other high orbital inclination systems implies that OU Vir is most likely a system for which a grazing eclipse of the hot spot occurs. The fact that we do not observe a white dwarf eclipse, constrains the inclination of the orbital plane within the range \(60^\circ < i < 75^\circ\). Considering that both the orbital inclination, \(i\), and the

\[ \frac{15 - 0.25}{25} \] 

More precisely the bright emission would appear almost in the lower left quadrant, i.e. ahead of the standard hot spot position which is expected in the upper left quadrant.

These limits have been computed assuming standard Roche lobe geometry for \(q = 0.15 - 0.25\) (see, e.g., Warner 1995, pg 33). The upper limit corresponds to the constraint of no white
two star components mass are unknown, we plot in Fig. 6 the $q$-$i$ and $q$-$M_2$ relations derived from formula (2.79) in Warner (1995), and valid for OU Vir (i.e. $K_1=103 \text{ km/sec}$, $P_{orb}=104.7 \text{ min}$, and $M_2=0.17M_\odot$ (a secondary star mass of $0.17M_\odot$ is predicted by the $P_{orb}$-$M_2$ relation in Howell et al. 2001, for systems having the same orbital period of OU Vir and before the orbital period minimum). The two dotted lines represent the $\pm 1\sigma$ error for the Keplerian velocity of $K_1=103 \text{ km/sec}$. Dashed lines represent the $q$-$M_2$ relation for constant values of the orbital inclination, $i = 60^\circ$ and $i = 75^\circ$.

![Fig. 6.](image)

In summary, BVRI band time resolved photometry of OU Vir in quiescence shows hot spot modulated light curve and deep eclipse as typical in high inclination SU UMa stars (e.g. OY Car Wood et al. 1989, Z Cha Wood et al. 1986, van Amerongen et al. 1990). However, the eclipse}

---

8 The WZ Sge hot spot fractional contributions have been computed using high speed multi-color photometry obtained on August 16th 1991 by W. Skidmore (private communication).

9 We are inclined to interpret the dramatic increase in flux from phase $\sim 0$. to 0.1 as a flare episode.
Fig. 7. Emission line (top) and continuum flux (bottom) vs. orbital phase. Both the continuum and the line flux were measured by the `ee` command in the IRAF task `splot`. The continuum flux results from the average of the two points marked by the cursor position; the line flux is the sum of the counts within the two cursor position after continuum subtraction. Different symbols are used to show different orbital cycles.

depth suggests that only a grazing eclipse of the hot spot is actually occurring in OU Vir, similarly to WZ Sge (e.g. Skidmore 1998) and V893 Sco (Bruch et al. 2000). Our photometry also detected cycle to cycle random brightness variations up to 0.25 mag, which -though smaller- are possibly similar to the cycle to cycle variation reported by Bruch et al. (2000) for V893 Sco. Random brightness variation are also observed in the OU Vir Hα emission line. The line flux light curve together with the line profile analysis suggests that these brightness variations occur in the whole disk and are not restricted to the impact region. No matter how we interpret the S-wave and the bright emission in the Doppler map, the OU Vir hot spot results suggest an optically thick region which does not produce strong emission lines. At last, both the red spectra continuum and the eclipse colors seem to indicate evidence of the secondary star, which has only rarely been detected in short orbital period dwarf novae (Z Cha, Bailey et al. 1981).

All these characteristics make OU Vir an extremely good target for the solution of the binary geometry and the modeling of the accretion system (i.e. disk plus hot spot). However, those results are presently made difficult by the observed strong flux variations and both the time and spectral resolving limits of our data sets. Fast speed photometry would be useful to derive the accretion disk flux distribution through eclipse analysis, and to interpret its brightness variation, while both IR spectroscopy and/or photometry should be pursued to possibly detect the secondary star, derive its temperature, Keplerian velocity, K2, and mass.

Acknowledgements. Observations reported here were obtained at the MMT Observatory, a joint facility of the University of Arizona and the Smithsonian Institution. This research was partially supported by NSF grant AST 98-10770 to SBH.

Table 3. Photometric magnitudes determined from the BVRI light curves in Fig. 1. Each magnitude was derived through a weighted average of the data points in the phase range specified. Last column (ID) roughly identifies the measured feature in the light curve. “average” refers to the average magnitude computed excluding the in-eclipse data points.

| Color, Phase range | Instr. Mag. | Used data points | ID |
|--------------------|-------------|-----------------|----|
| B 0.14-0.73        | 18.23±0.01  | 62              | average |
| B 0.79-0.96        | 18.00±0.02  | 14              | pre-eclipse hump |
| B 0.49-0.71        | 18.29±0.01  | 22              | secondary minimum |
| V 0.10-0.71        | 18.08±0.01  | 99              | average |
| V 0.52-0.70        | 18.16±0.01  | 32              | secondary minimum |
| R 0.15-0.70        | 17.18±0.01  | 54              | average |
| R 0.80-0.96        | 17.04±0.01  | 15              | pre-eclipse hump |
| R 0.53-0.70        | 17.24±0.01  | 14              | secondary minimum |
| I 0.17-0.88        | 17.35±0.01  | 72              | average |
| I 0.76-0.88        | 17.28±0.02  | 11              | pre-eclipse hump |
| I 0.51-0.65        | 17.42±0.02  | 14              | secondary minimum |

Table 5. Best fit parameters of our radial velocity measurements. Best fit parameters are in bold face (see text for more explanations).

| Method            | Em. Line | $\gamma$ | $K_1$ | $\phi_{R/B}$ |
|-------------------|----------|----------|-------|--------------|
| Double Gaussian    | Hα       | 243±14   | 103±20| 0.28±0.03    |
| line flux barycenter | Hα       | 247±14   | 125±19| 0.31±0.03    |
