Geochemical Characteristics of Amphibolites in Parts of Iseyin-Oyan Schist Belt, Southwestern Nigeria

Maryam O. Abdus-Salam, Anthony T. Bolarinwa, Akinade S. Olatunji and Victoria Omotunde

ABSTRACT

Amphibolite is an important lithologic unit of the Nigerian basement complex that are commonly intercalated within metasedimentary sequences. Disseminated grains of sulphide minerals and base metal deposits are reported to occur in amphibolites and some other lithologies in other schist belts of Nigeria apart from the Iseyin-Oyan schist belt. Detailed geochemical study of amphibolitic rocks in this schist belt is scarce in literature, whereas none exist for the area under study, thus, this study is aimed at delineating the amphibolites within the Iseyin-Oyan schist belt around Itasa area with detail appraisal of their petrography and geochemical characteristics. A geologic field mapping was undertaken, and fresh representative amphibolite samples were obtained. Petrographic and geochemical studies of the samples were carried out with a view to understand their nature and petrogenetic characteristics. Geochemical data were elucidated using diverse geochemical discrimination diagrams. The amphibolites occur as lenses of small to large rocky boulders trending NNE-SSW and are essentially basal to quartz mica schist. Modal compositions revealed that they are dominantly composed of hornblende and plagioclase. XRD and mineral chemistry revealed that the plagioclase ranged from andesine to anorthite while hornblende is mainly magnesiohornblende. Geochemical data and discrimination diagrams revealed that the amphibolites are formed from basaltic to basaltic-andesitic to andesitic-andesite protolith that are of tholeitic nature and had suffered crustal contamination. Tectonic discrimination diagrams indicated that the rocks were emplaced in the Mid Ocean Ridge but had been affected by collision due to Pan African Orogenic tectonic event.

Keywords: Amphibolites, Crustal contamination, Geochemical characteristics, Iseyin-Oyan schist belt.

I. INTRODUCTION

The Nigerian basement complex constitutes the most extensive assemblage of the Trans-Saharan mobile belt interposed between the cratons of West Africa and Congo (Fig. 1) [1]. Petro-lithologic groups within the Basement include the migmatite-gneisses quartzite complex, the schist belt, the Pan African Older granites and the Undeformed dykes [2]-[5]. A number of north- southerly trending Proterozoic rocks, the schist belts, occur more prominently within the western part of the basement. They are low-medium grade supracrustal rocks which are composed of lithologies including marbles, calc-gneisses, psammites and mafic—ultramafic units dominated by amphibolite. These schist belts include Iseyin-Oyan, Maru, Anka, Zuru, Kazaure, Kushaka, Igarra, Wonaka, Karaukarau, Zungeru-Birnin Gwari and Ilesha [6].

There are little records of detailed geological investigation carried out on various units of the Precambrian Basement Complex in the Iseyin-Oyan Schist Belt compared to other schist belts in Nigeria. Most of the rocks are generally described as undifferentiated schists and granites in the geological map of Nigeria [7] with no isolation of amphibolite lenses that dotted the area.

Amphibolites are important components of the Nigerian basement complex that are commonly found as ovoid-shaped bodies intercalated within metasedimentary sequences [8]. Disseminated grains of sulphide mineral and base metal deposits have been reported to occur in amphibolites and some other lithologic units in other schist belts of Nigeria [9] with the exception of Iseyin-Oyan schist belt. Furthermore, detailed geochemical study of these amphibolitic rocks in Iseyin-Oyan schist belt is scarce in literature. This study was therefore undertaken in order to delineate the amphibolites of the Iseyin-Oyan schist belt around the Itasa area, through detail appraisal of their geochemistry in order to understand their nature and petrogenetic characteristics.
II. STUDY LOCATION

The study area lies within the Iseyin-Oyan schist belt, around Itasa area, southwestern part of Nigeria. The area includes villages like Ibudo Apata, Imadi and Idi Ero and delineated by latitude 8° 00’ and 8° 08’ N and longitude 3° 00’ and 3° 07’ E. The area is characterized by rugged topography with elevations ranging from about 200 to about 500m. It is located within a tropical humid climate region with an annual temperature of 21 °C and 34 °C. The prevailing seasons are the Rainy (April to October) and the Dry Season (November to March). The average annual mean rainfall is 1,250 mm [10].

The exposed lithologies within the study area are quartz mica schist, amphibolite, granite gneiss, quartz diorite, biotite alkali granite and porphyritic granite (Fig. 2). The amphibolites, which are the focus of this study, trend NNE-SSW and occur in close association with the quartz mica schist. They are restricted to the western and central parts of the area.

III. METHODS

Geological field mapping and collection of amphibolite samples were undertaken within the Iseyin-Oyan schist belt around Itasa area. Thin sections of the samples were prepared at the thin section laboratory of the Department of Geology, University of Ibadan, Nigeria. The thin sections were examined using binocular petrological microscope at the Department of Geology, The Polytechnic, Ibadan, Nigeria. X-ray diffraction (XRD) analyses were conducted for the qualitative phase identification of the minerals within the amphibolite using PANalytical Empyrean X-ray Diffractometer with a graphite monochromated Cu Kα radiation source operating at 40 kV and 40 mA generating set.
over 5° to 80° 2θ angular range. Mineral chemistry of the essential and accessory minerals in the amphibolites were determined using a Scanning Electron Microscope (SEM) equipped with an Energy Dispersive Spectrometer that has an INCA 350 software and operating at 20 - 25 kV accelerating voltage, 15–20 nA beam current and counting times of 20–35 s per element. Quantitative analysis of the major, trace and rare earth elements within amphibolites were determined using Xray Fluorescence spectroscopy (XRF) and Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES) at the University of Wolverhampton, United Kingdom. Major oxides and trace elements concentrations were determined on powder pressed pellet using XRF whereas rare earth elements were analysed using ICP-OES after sample digestion with fusion following the method described by Zhang et al [11].

IV. RESULTS AND DISCUSSIONS

A. Petrography

The amphibolites occur as lensoid bodies of small to large rocky boulders (Fig. 3) trending NNE-SSW. Field relationships show that they are essentially basal to quartz mica schist. They occur at the western and eastern parts of Itasa area, usually along river channels.

They are medium to coarse grained greenish rocks with modal compositions showing hornblende (40-55 vol.%) and plagioclase (10-30 vol.%) as the dominant minerals (Error! Reference source not found.). Other subordinate minerals include quartz (3 -6 vol.%), epidote (0-11 vol.%), titanite (2 to 9 vol. %), biotite, zircon (0-1 vol. %), apatite (0-1 vol. %) and opaque minerals (0-1 vol. %). X- Ray diffractograms (Fig. 5) of the amphibolite is consistent with the petrographic information. Magnesiohornblende, anorthite, epidote, augite and quartz, were identified on the diffractograms. Based on the mineral paragenesis, the amphibolites reached amphibolite facies conditions.

Backscattered electron images of minerals in the amphibolite are shown in Fig. 6. Mineral chemistry revealed that hornblende is mainly magnesio-hornblende, which are subhedral to anhedral and have random or preferred orientations. It is pleochroic from red to brown and incorporates inclusions. The plagioclase ranged from andesine to anorthite composition and are characterised by albite twin lamella of narrow to broad bands indicating compositional variation. Zircon and apatite occur as inclusions in magnesio-hornblende within the amphibolites. Opaque minerals are usually titanite, titanomagnetite and magnetite. Mineral alteration products include apatite and altered pyroxenes and amphiboles.

B. Geochemistry

Chemical compositions of the amphibolites (Table 1) revealed significant variation. The chemical data interpreted using the Niggli numbers suggested by Leake [12] indicated that the amphibolites are characteristic of mafic magmatic rocks. Positive correlation between Cr and Ni versus mg are typical of rocks formed from igneous progenitors [12]. However, low contents of Ni and Cr but high Sr, Ba and Zr indicated that the amphibolites have crustal inputs [12]. Niggli discrimination diagrams (Fig. 7) revealed that they are mid-stage differentiated igneous rock with slight scattering confirming crustal input.
Fig. 4. Photomicrograph of amphibolites (Left: Cross Polarized light; and right: Plane polarised light) showing abundance of hornblende and plagioclase with minor titanite, apatite (ap) and opaque.

Fig. 5 X-ray diffractograms of the amphibolites under study.

Fig. 6. Backscattered Electron images of the Amphibolites showing Anorthite.
The protoliths of the amphibolites are basalt and basaltic-andesite (Fig. 8a-b) on the Zr/Ti against Nb/Y [13] diagrams; and the Al-Fe³⁺-Ti-Mg ternary plot [14].

The trace elements distribution intermediate between continental and oceanic basalts. The tholeiitic nature was confirmed on the [15] petrogenetic plot (Fig. 8c). Amphibolites with ocean floor affinity have been reported in Zuru schist belt [16], Obudu Plateau [17] and some of the Ile-Ilesha schist belt [18]. This contrasted continental tholeiites reported in another parts of Ilesha [8] and Guguruji schist belt [19]. Tholeiitic magma is characteristic of mafic volcanism in the Precambrian and occurred nearly to the exclusion of alkali basalts for the first three-quarters of geological time [20].

The chondrite [21]-normalized pattern (Fig. 8d) revealed a LREE > HREE trend which suggested possible crustal input. There is no apparent positive Eu anomaly suggestive of moderate plagioclase fractionation in the rocks and characteristics of basic rocks that have been granitized.

The Zr versus Zr/Y diagram [22] and Zr-Nb-Y ternary plots [23] indicated that the amphibolite were emplaced between mid ocean ridge (divergent) and within continental plate and volcanic arc (divergent) settings (Fig. 9). These suggested that the protolith were mantle derived fractionated tholeiitic magma of mid oceanic character deposited in a back-arc environment and possibly got metamorphosed during the Pan-African orogeny.

### TABLE 1: MAJOR OXIDE (WT.%), TRACE AND RARE EARTH ELEMENTS (PPM) CONCENTRATIONS IN THE AMPHIBOLITES OF THE STUDY AREA

| Oxides | Amph96 | Amph92 | Amph55 | Amph30 |
|--------|--------|--------|--------|--------|
| SiO₂   | 53.75  | 53.46  | 49.24  | 53.77  |

Discrimination diagrams (a) Zr/Ti against Nb/Y (after Pearce, 1996); (b) Al-Fe-Ti-Mg (after Jensen, 1976) (c) AFM (Irvine and Baragar, 1971) showed the amphibolites are mostly tholeiitic character and (d) Chondrite normalized REE pattern for the amphibolites in the study area.

Fig. 9. (a) Zr-Zr/Y classification diagram (after Pearce and Norry 1979) and (b) Zr-Nb-Y discrimination diagram (Meschede 1986) showing the dominance of VAB- NMORB composition of the amphibolites AI-AII. Within-plate alkali basalt and within Plate tholeiites; B. E type MORB; C. Within Plate tholeiites and volcanic-arc basalt; D. N-MORB and volcanic-arc basalt.

V. CONCLUSION

The amphibolites within the Iseyin-Oyan schist belt around Itasa area occur as lenses of small to large rocky boulders within quartz mica schist. The amphibolites are dominated by magnesio-hornblende and plagioclase of andesine to anorthite composition with minor minerals including quartz, epidote, titanite, zircon and apatite. Chemical data, Niggli variables and discrimination plots indicated that the protolith are basalt to basaltic- andesite with tholeiitic affinity. Trace and rare element composition suggested that they had suffered crustal contamination, such that they no longer showed the normal positive Eu anomaly characteristics of basic-ultrabasic igneous protolith.

ACKNOWLEDGMENT

This publication is part of the Ph.D. thesis of the first author, funded by the African Union through the Pan-African University institute of life and earth sciences (including health and agriculture), University of Ibadan, Nigeria. Reviewers are highly appreciated for their comments and criticisms towards the improvement of this paper.
