The Laws of Motion of the Broker Call Rate in the United States

Alex Garivaltis*

October 19, 2021

Abstract

In this paper, which is the third installment of the author’s trilogy on margin loan pricing, we analyze 1,367 monthly observations of the U.S. broker call money rate, which is the interest rate at which stock brokers can borrow to fund their margin loans to retail clients. We describe the basic features and mean-reverting behavior of this series and juxtapose the empirically-derived laws of motion with the author’s prior theories of margin loan pricing (Garivaltis 2019a-b). This allows us to derive stochastic differential equations that govern the evolution of the margin loan interest rate and the leverage ratios of sophisticated brokerage clients (namely, continuous time Kelly gamblers). Finally, we apply Merton’s (1974) arbitrage theory of corporate liability pricing to study theoretical constraints on the risk premia that could be generated in the market for call money. Apparently, if there is no arbitrage in the U.S. financial markets, the implication is that the total volume of call loans must constitute north of 70% of the value of all leveraged portfolios.

1 Introduction

This paper is inspired chiefly by two of the author’s theoretical formulas for margin loan pricing by stock brokers (Garivaltis 2019a-b):

1. **The instantaneous monopoly price of margin loans to Kelly (1956) gamblers:**

   \[ r^*_L = \frac{1}{2} r_B + \frac{1}{2} (\nu - \sigma^2 / 2) \]  

2. **The negotiated interest rate under instantaneous Nash (1950) Bargaining\(^1\) with Kelly gamblers:**

   \[ r^*_L = \frac{3}{4} r_B + \frac{1}{4} (\nu - \sigma^2 / 2) \].

In these formulas, \( r^*_L \) denotes the (continuously-compounded) margin loan interest rate charged by the broker over the differential time step \([t, t+dt]\), where \( \nu := \mu - \sigma^2 / 2 \) is the asymptotic (or logarithmic) growth rate of the stock market index, \( \sigma \) is the annual volatility, and \( \mu \) is the annual (arithmetic) drift rate. \( r_B \) denotes the broker’s cost of funding (“broker call money rate”) for the duration \([t, t+dt]\). These formulas are of great interest on account of their simplicity and their practicality; naturally, the broker charges more if the underlying growth opportunity

\[ dS_t := \mu \, dt + \sigma \, dW_t \]  

\[ d(\log S_t) = (\mu - \sigma^2 / 2) \, dt + \sigma \, dW_t \]  

\(^1\)This formula corresponds to one particular threat point, whereby the broker refuses to issue the client a margin loan (or the client refuses to borrow any money). For the general Nash Bargaining solution (relative to an arbitrary threat point), cf. with Garivaltis (2019b). If the monopoly market structure itself is taken as the threat point, then the negotiated interest rate will of course be lower than the monopoly price. Note that the threat of no margin loans at all is apparently so severe that the gambler is suddenly willing to pay more than the monopoly price.
is more favorable (higher $\nu$, lower $\sigma$). Because all the action (the broker posts a monopoly price, or the principals Nash bargain over both the price and quantity of margin loans) happens over the differential time step $[t, t + dt]$, the formulas apply equally well to a general situation whereby the stock market index $S_t$ is governed by time- and state-dependent parameters $\mu(S_t, t)$ and $\sigma(S_t, t)$. The affine relationships (3) and (4) imply that the net interest margin $r^*_L - r_B$ must shrink whenever the broker call rate $r_B$ increases; 

\begin{align*}
\text{The purpose of this article, then, is to use empirical data to divine the general laws of motion of the U.S. broker call rate } r_B(t), \text{ and to study the logical consequences for the random behavior of margin loan interest rates, risk premia, and the leverage ratios of continuous time Kelly gamblers. The U.S. broker call money rate, which is published daily in periodicals like The Wall Street Journal and Investor’s Business Daily, is so-named because stock brokers must be prepared to repay these funds immediately upon “call” from the lending institution.}

The paper is organized as follows. Section 2 describes our data set, which consists of some 1,367 monthly observations (covering the years 1857-1970) published by the Federal Reserve Bank of St. Louis (FRED). We estimate the mean-reverting (monthly) specification

\begin{align*}
\text{Call Rate}_{t+1} = 3.943 + 0.597(\text{Call Rate}_t - 3.943) + 2.362\epsilon_t, \quad (7)
\end{align*}
the broker call rate, we develop some out-of-sample forecasts based on the empirical AR(2) model

\[
\text{Call Rate}_{t+1} = 1.215 + 0.456 \cdot \text{Call Rate}_t + 0.235 \cdot \text{Call Rate}_{t-1} + 2.297 \epsilon_t. \quad (8)
\]

Section 3 juxtaposes the empirical specifications (7) and (8) with the theoretical pricing formula (3) to derive stochastic differential and difference equations that must govern the evolution of the margin loan interest rates charged by stock brokers. As an application, we deduce and simulate the implied law of motion for the leverage ratios of continuous time Kelly gamblers. Finally, section 4 applies Merton’s (1974) arbitrage theory of corporate liability pricing to derive theoretical constraints on the risk premia that could be generated in the market for call money. Based on Fortune’s (2000) suggestion, we model a situation whereby stock brokers are not willing or able to hedge the default risks of their margin loans; at the same time, they must pledge their customers’ securities as collateral to the banks and financial institutions who lend in the market for call money. This environment generates positive risk premia because the banks are exposed to a credit event whereby the retail client defaults on his margin loan, and the broker in turn defaults on its debt to the banks that (partially) funded the loan. Our numerical work indicates that, in comparing the prevailing (low) U.S. Treasury yields with the broker call rate (which is 4.25% as of this writing), the implied loan-to-value ratios of retail borrowers are north of 70 percent. This is an absurd figure (for one thing, it contradicts U.S. Regulation-T), and it seems to indicate that U.S. banks are earning substantial arbitrage profits on the spread of the call rate over the risk-free rate. Section 5 concludes the paper.
2 Broker Call Rate

2.1 Basic Description of the Data

We proceed to analyze $T := 1,367$ monthly observations of the broker call money rate (January 1, 1857 through November 1, 1970, annual interest rates, in percent) as published by the Federal Reserve Bank of St. Louis’ macrohistory database (FRED). In order to find agreement with the author’s prior work on margin loan pricing (Garivaltis 2019a-b), we must deal with the continuously-compounded annual interest rate, as follows:

$$y_t := \text{Continuously-Compounded Interest Rate}_t$$

$$= 100 \cdot \log(1 + \text{Interest Rate}_t/100)$$

$$= \text{Interest Rate}_t - \frac{(\text{Interest Rate}_t)^2}{200} + \frac{(\text{Interest Rate}_t)^3}{30,000} - \cdots$$

(9)

Figure 1 gives a plot of the time series $(y_t)_{t=1}^T$; the grey bars on the figure indicate NBER recessions, during which rates have usually fallen precipitously. For the sake of smoothing out the choppy appearance of $(y_t)_{t=1}^T$, Figure 2 plots the 12-month simple moving average

$$\bar{y}_t := \frac{1}{12} \sum_{j=0}^{11} y_{t-j}. \quad (10)$$

Table 1 contains basic descriptive information about the broker call rate; in our sample, the call money rate averaged 3.95%, with a standard deviation of 2.95% from its long-run mean. The mean absolute deviation was 1.95%. Although at times the broker call rate has spiked to levels as high as 47.8%, the historical 95th percentile is a more palatable 8.16%.
Figure 3 shows a histogram of the realizations \((y_t)_{t=1}^{1367} = (\text{Call Rate}_t)_{t=1}^{1367}\). On that score, making use of Gaussian basis functions and a bandwidth of \(h := 0.502\), we have the estimated population density function

\[
\hat{f}(y) := 0.000581 \sum_{t=1}^{1367} 0.138(y - \text{Call Rate}_t)^2,
\]

which is plotted in Figure 4. To help visualize the internal correlation structure of the call money rate, Figure 5 gives a plot of the sample autocorrelation function

\[
\hat{\rho}_j := 0.0000843 \sum_{t=j+1}^{1367} (y_t - 3.95)(y_{t-j} - 3.95),
\]

where \(j \in \{0, ..., 12\}\) denotes the number of lags, in months. The sample correlation coefficient for successive monthly observations is \(\hat{\rho}_1 = 59.7\%\). In order to control for any confounding effects that the interim observations \((y_{t-j+1}, y_{t-j+2}, ..., y_{t-1})\) could possibly have on the observed relationship between \(y_{t-j}\) and \(y_t\), Figure 6 supplements the sample correlogram with a 24-month plot of the sample partial autocorrelation function. As illustrated by the figure, the partial autocorrelations start to lose their statistical significance for lags in excess of 12 months.

### 2.2 Reversion to the Mean

Drawing some inspiration from the sample autocorrelation function as depicted in Figure 5, we proceed to estimate a stationary first-order autoregressive model of \((y_t)_{t=1}^T\). This amounts to the linear stochastic difference equation

\[
\text{Call Rate}_{t+1} = \alpha + \rho \cdot \text{Call Rate}_t + \sigma \epsilon_t,
\]
or equivalently,

\[(1 - \rho L) y_{t+1} = \alpha + \sigma \epsilon_t, \tag{14}\]

where \(L\) denotes the lag operator. The deep parameters are \(\alpha, \rho,\) and \(\sigma,\) and the stochastic shocks \((\epsilon_t)_{t=1}^T\) are assumed to be unit white noise, e.g. they are serially uncorrelated, \(\mathbb{E}[\epsilon_t] \equiv 0,\) and \(\text{Var}[\epsilon_t] \equiv 1.\) The contemporaneous disturbance \(\epsilon_t\) is assumed to be uncorrelated with \(\text{Call Rate}_t.\)

Under this terminology, the long-run mean of the (continuously-compounded) interest rate is given by

\[
\mu := \mathbb{E}[\text{Call Rate}_t] = \frac{\alpha}{1 - \rho}, \tag{15}
\]
and the stationary variance and standard deviation are equal to

\[ v := \text{Var}[\text{Call Rate}_t] = \frac{\sigma^2}{1 - \rho^2} \quad (16) \]

and

\[ s := \text{Std}(\text{Call Rate}_t) = \sqrt{v} = \frac{\sigma}{\sqrt{1 - \rho^2}}. \quad (17) \]

Of course, the (aptly named) parameter \( \rho \) in this AR(1) model is equal to the Pearson correlation coefficient of successive monthly interest rates:

\[ \rho = \text{Corr}(\text{Call Rate}_t, \text{Call Rate}_{t-1}). \quad (18) \]

More generally (cf. Fuller 1976), the population autocorrelation function of the pro-
Basic Quantitative Description of the Broker Call Money Rate (1857:01-1970:11)

| Sample Statistic                  | Value     |

| 5$^{th}$ percentile               | 1%        |
| 50$^{th}$ percentile (median)     | 3.69%     |
| 95$^{th}$ percentile              | 8.16%     |

Table 1: Summary statistics for monthly observations of the U.S. broker call money rate.

cess ($y_t$)$_{t=1}^\infty$ is given by

$$\text{Corr}(\text{Call Rate}_t, \text{Call Rate}_{t-j}) = \rho^j. \quad (19)$$

If we let $\theta := 1 - \rho$ and re-arrange the empirical specification (13), we obtain the following equivalent representations:

$$\text{Call Rate}_{t+1} - \mu = \rho(\text{Call Rate}_t - \mu) + \sigma \epsilon_t, \quad (20)$$

$$\Delta(\text{Call Rate}_t) = -\theta(\text{Call Rate}_t - \mu) + \sigma \epsilon_t, \quad (21)$$

where $\theta$ represents the rate of monthly mean reversion per 100 basis points of deviation from the equilibrium level. The coefficients $\alpha, \rho$ can be recovered from the new parameters $\mu, \theta$ via the relations $\alpha = \theta \mu$ and $\rho = 1 - \theta$.

Table 2 gives the parameter estimates that obtain when fitting the empirical rela-
The Laws of Motion of the Broker Call Rate in the United States

A. Garivaldis

Figure 3: **Histogram for the U.S. broker call rate (continuously-compounded, in percent).** Bin width = 25 basis points; values > 10% are not pictured.

The relationship $y_{t+1} = \alpha + \rho y_t + \sigma \epsilon_t$ via ordinary least squares (OLS). The linear regression is illustrated in Figure 7, which plots the broker call rate versus its lagged values. Thus, our empirical law of motion for the call money rate is

$$\text{Call Rate}_{t+1} = 3.943 + 0.597(\text{Call Rate}_t - 3.943) + 2.362 \epsilon_t. \quad (22)$$

$$\Delta(\text{Call Rate}_t) = -0.403(\text{Call Rate}_t - 3.943) + 2.362 \epsilon_t. \quad (23)$$

This means that for every 100 basis points of deviation from its long-run average of 3.94%, the broker call rate is expected to close the gap at a rate of 40 basis points per month. However, this mean-reverting behavior is corrupted by random disturbances whose average (root-mean-squared) magnitude is 2.36% per month.
Solving the first-order difference equation (13) for Call Rate\(_t\) in terms of Call Rate\(_0\), one gets the expression (cf. Hamilton 1994)

\[
\text{Call Rate}_t = \frac{1}{1 - \rho L} \left( \alpha + \sigma \epsilon_{t-1} \right)
= \mu + \rho^t (\text{Call Rate}_0 - \mu) + \sigma \sum_{s=0}^{t-1} \rho^{t-1-s} \epsilon_s
= 3.943 + 0.597^t (\text{Call Rate}_0 - 3.943) + 2.362 \sum_{s=0}^{t-1} 0.597^{t-1-s} \epsilon_s.
\]

(24)

Thus, our general forecast for the broker call rate \(t\) months hence (normalizing today’s...
The Laws of Motion of the Broker Call Rate in the United States  A. Garivaltis

Figure 5: 12-month sample correlogram for the U.S. broker call rate.

The corresponding root-mean-squared forecast error is

\[ \text{Std}(\text{Call Rate}_t | \text{Call Rate}_0) = \sqrt{s^2 \sqrt{1 - \rho^2} \sqrt{1 - \rho^2 t}} = 2.944 \sqrt{1 - 0.356^t}. \]  

\[ \text{Std}(\text{Call Rate}_t | \text{Call Rate}_0) = \frac{s \sqrt{1 - \rho^2} \sqrt{1 - \rho^2 t}}{\sqrt{1 - \rho^2}} = 2.944 \sqrt{1 - 0.356^t}. \]  

\[ \text{Std}(\text{Call Rate}_t | \text{Call Rate}_0) = \frac{\sigma}{\sqrt{1 - \rho^2}} \sqrt{1 - \rho^2} = s \sqrt{1 - \rho^2 t} = 2.944 \sqrt{1 - 0.356^t}. \]  

\[ \text{Std}(\text{Call Rate}_t | \text{Call Rate}_0) = \frac{\sigma}{\sqrt{1 - \rho^2}} \sqrt{1 - \rho^2} = s \sqrt{1 - \rho^2 t} = 2.944 \sqrt{1 - 0.356^t}. \]

(25)

Figure 8 plots the root-mean-squared forecast error against time for \( t \in \{0, ..., 6\} \).

Example 1 (Out-of-Sample Predictions). As of this writing, Bankrate.com reports the following information about the U.S. call money rate:
One year ago, the broker call rate was \( y_0 := 3.5\% \), \( (y_0 - \mu = -0.443) \).

One month ago, the broker call rate was \( y_{11} = 4.25\% \), \( (y_{11} - \mu = 0.307) \).

The current U.S. call money rate (as of this writing) is also \( y_{12} = 4.25\% \).

Thus, from the standpoint of a month ago, today’s call money rate would have been forecasted to be 4.13%, for a prediction error of 0.12%. From the standpoint of a year ago, today’s call money rate would have been forecasted to be 3.94%, for a prediction error of 0.31%. These errors compare favorably with the root-mean-squared errors plotted in Figure 8.

2.3 AR(2) Model

Taking our cue from the fact that Bankrate.com only reports the two most recent monthly observations of the broker call rate, we proceed to estimate a (stationary)
OLS Estimates for the Mean-Reverting Specification
($R^2 = 36\%$; standard errors in parentheses)

| Parameter/Regression Statistic | Estimate/Value | Conf. Interval |
|-------------------------------|----------------|----------------|
| $\alpha$ (Intercept)          | 1.587*** (0.107) | [1.377,1.797] |
| $\rho$ (Correlation of successive observations) | 0.597*** (0.022) | [0.555,0.64] |
| $1/\rho$ (Root of $1 - \rho L$) | 1.674 |  |
| $\theta = 1 - \rho$ (Monthly rate of mean-reversion) | 0.403 |  |
| $\mu = \alpha / \theta$ (Long-run mean) | 3.943 |  |
| $\sigma$ (Root-mean-squared prediction error) | 2.362 |  |
| $s := \sigma / \sqrt{1 - \rho^2}$ (Long-run standard deviation) | 2.944 |  |
| Mean absolute residual | 1.124 |  |
| 5th percentile absolute residual | 0.0958 |  |
| 50th percentile (median) absolute residual | 0.853 |  |
| 95th percentile absolute residual | 2.787 |  |

Table 2: Parameter estimates for mean-reverting model of the U.S. broker call money rate.

A second-order autoregressive model for the sake of lowering our root-mean-squared prediction error. Thus, we have the empirical specification

$$y_{t+1} = c + \phi_1 y_t + \phi_2 y_{t-1} + \sigma \epsilon_t,$$

(27)

or equivalently,

$$(1 - \phi_1 L - \phi_2 L^2) y_{t+1} = c + \sigma \epsilon_t.$$

(28)

The long-run mean is

$$\mu := \mathbb{E}[y_t] = \frac{c}{1 - \phi_1 - \phi_2},$$

(29)

and the unconditional variance (cf. Fuller 1976) is

$$v := \text{Var}[y_t] = \frac{(1 - \phi_2)\sigma^2}{(1 + \phi_2)[(1 - \phi_2)^2 - \phi_1^2]}.$$

(30)
When expressed in mean-deviation form, our empirical specification amounts to

\[ y_{t+1} - \mu = \phi_1(y_t - \mu) + \phi_2(y_{t-1} - \mu) + \sigma \epsilon_t, \]  
\[ \text{or equivalently,} \]

\[ \Delta y_t := y_{t+1} - y_t = -(1 - \phi_1)(y_t - \mu) + \phi_2(y_{t-1} - \mu) + \sigma \epsilon_t. \]  

Table 3 summarizes the results of the autoregression. Our estimated relationship is

\[
\text{Call Rate}_{t+1} = 1.215 + 0.456 \cdot \text{Call Rate}_t + 0.235 \cdot \text{Call Rate}_{t-1} + 2.297 \epsilon_t. \]
Figure 8: **Root-mean-squared forecast errors (in percent) for up to 6 months ahead.**

For the sake of calculating the general forecast \( \mathbb{E}[y_t|y_0, y_1] \), we must solve the following (deterministic) difference equation (cf. Spiegel 1971):

\[
y_{t+1} = c + \phi_1 y_t + \phi_2 y_{t-2}.
\]  
(34)

A particular solution is of course given by \( y_t^p \equiv \mu \). In order to solve the associated homogeneous equation

\[
y_{t+1} = \phi_1 y_t + \phi_2 y_{t-2},
\]  
(35)

we require the roots of the characteristic equation

\[
\lambda^2 - \phi_1 \lambda - \phi_2 = 0,
\]  
(36)
which are

$$\lambda_{1,2} = \frac{\phi_1 \pm \sqrt{\phi_1^2 + 4\phi_2}}{2} = 0.764, -0.308. \tag{37}$$

Thus, the general solution of the difference equation (34) is

$$
\mathbb{E}[y_t|y_0, y_1] = \mu + \frac{1}{\lambda_2 - \lambda_1}\left\{[\lambda_2(y_0 - \mu) - (y_1 - \mu)]\lambda_1^t + [y_1 - \mu - \lambda_1(y_0 - \mu)]\lambda_2^t\right\}
= 3.938 - 0.933\left\{[-0.308(y_0 - 3.938) - (y_1 - 3.938)]0.764^t + [y_1 - 3.938 - 0.764(y_0 - 3.938)](-0.308)^t\right\}. \tag{38}
$$

Figure 10 compares the 12-month forecasts of our estimated AR(1) and AR(2) models, given the two most recent observations $y_0 := 4.25$ and $y_1 := 4.25$. Note that the

Table 3: Parameter estimates for AR(2) model of the U.S. broker call money rate.

AR(2) forecast exhibits a significantly slower rate of mean-reversion than its AR(1) counterpart. On that score, Figure 11 plots the two models’ responses to an exogenous 100 basis point impulse in the broker call rate. After 6 months, the persistent effect on the broker call rate amounts to 14 basis points under the AR(2) model; at the 12-month mark, the marginal effect dissipates to just 3 basis points.

2.4 Vasicek Model

To better understand the short-term (intra-month) fluctuations of the broker call rate, we use our monthly AR(1) parameter estimates to help fit an Ornstein-Uhlenbeck model of interest rate evolution in continuous time (cf. Mikosch 1998). Vasicek (1977) was the first researcher who used Ornstein-Uhlenbeck processes to model the mean-reverting behavior of interest rates. In our context, we have the following stochastic
The Laws of Motion of the Broker Call Rate in the United States

A. Garivaldis

Figure 10: 12-MONTH FORECAST COMPARISON FOR AR(1) AND AR(2) MODELS OF THE BROKER CALL RATE, GIVEN THE TWO MOST RECENT OBSERVATIONS $y_0 := 4.25$ AND $y_1 := 4.25$ (AS OF 5/18/2019).

differential equation (the time $t$ being measured in months):

$$d(\text{Call Rate}_t) = -\theta (\text{Call Rate}_t - \bar{\mu}) \, dt + \sigma \, dW_t.$$  \hfill (39)

Equivalently, we have the integrated form (cf. Mikosch 1998)

$$\text{Call Rate}_t = \text{Call Rate}_0 - \bar{\theta} \int_0^t (\text{Call Rate}_s - \bar{\mu}) \, ds + \sigma W_t,$$  \hfill (40)

where $W_t$ is a standard Brownian motion and $dW_t := \epsilon \sqrt{dt}$ is its instantaneous change in position over the differential time step $[t, t+dt]$. The parameter $\bar{\mu} := \mathbb{E}[\text{Call Rate}_t]$ represents the stationary mean, or long-run equilibrium level, of the broker call money.
The parameter

$$-\bar{\theta} := \frac{\mathbb{E}[d(\text{Call Rate}_t)|\text{Call Rate}_t]}{\text{Call Rate}_t - \bar{\mu}}$$

(41)

denotes the instantaneous rate of mean-reversion, e.g. the expected rate of change in the interest rate as a percentage of its current deviation from the long-run average.

Finally, the parameter

$$\bar{\sigma}^2 := \frac{\operatorname{Var}[d(\text{Call Rate}_t)|\text{Call Rate}_t]}{dt}$$

(42)

represents the local variance of interest rate changes per unit time.

The solution of the Ornstein-Uhlenbeck equation (cf. Mikosch 1998) is

$$\text{Call Rate}_t = \bar{\mu} + e^{-\bar{\theta}t}(\text{Call Rate}_0 - \bar{\mu}) + \bar{\sigma} \int_0^t e^{-\bar{\theta}(t-s)}dW_s,$$

(43)
and the stationary (long-term) standard deviation is

\[ \text{Std}(\text{Call Rate}_t) = \frac{\sigma}{\sqrt{2\bar{\theta}}}. \]  

(44)

The corresponding \( t \)-month ahead forecast is

\[ \mathbb{E}[\text{Call Rate}_t | \text{Call Rate}_0] = \bar{\mu} + e^{-\bar{\theta}t}(\text{Call Rate}_0 - \bar{\mu}), \]  

(45)

and the root-mean-squared forecast error is

\[ \text{Std}(\text{Call Rate}_t | \text{Call Rate}_0) = \frac{\sigma}{\sqrt{2\bar{\theta}}} \sqrt{1 - e^{-2\bar{\theta}t}}. \]  

(46)

In order to reconcile the conditional forecast function \([45]\) with the AR(1) forecast \( \mathbb{E}[\text{Call Rate}_t | \text{Call Rate}_0] = \mu + \rho^t(\text{Call Rate}_0 - \mu) \), we must have

\[ \bar{\mu} := \mu = 3.943 \] and

(47)

\[ \bar{\theta} := -\log \rho = 0.516. \]  

(48)

In order to reconcile the long-run standard deviation \([44]\) with its AR(1) counterpart \( s = \sigma/\sqrt{1 - \rho^2} \), we must have

\[ \sigma := s \sqrt{-2\log \rho} = \sigma \sqrt{\frac{-2\log \rho}{1 - \rho^2}} = 2.99. \]  

(49)

Thus, the following three equations summarize our estimated law of (continuous) motion for the U.S. broker call rate.
The Laws of Motion of the Broker Call Rate in the United States

A. Garivaldis

Figure 12: Intra-month simulation of the (continuously-compounded) U.S. broker call rate ($y_0 := 4.25$).

Differential Form:

$$d(\text{Call Rate}_t) = -0.516(\text{Call Rate}_t - 3.943)\, dt + 2.99\, dW_t, \quad (50)$$

Integral Form:

$$\text{Call Rate}_t = \text{Call Rate}_0 - 0.516 \int_0^t (\text{Call Rate}_s - 3.943)\, ds + 2.99W_t, \quad (51)$$

Explicit Form:

$$\text{Call Rate}_t = 3.943 + 0.597t(\text{Call Rate}_0 - 3.943) + 2.99 \int_0^t 0.597^{t-s} dW_s. \quad (52)$$

Figure 12 plots the result of an intra-month simulation of the U.S. broker call rate, starting from an initial level of $y_0 := 4.25$. 

22
3 Implications for Margin Loan Pricing

For the sake of this section, so as to avoid any confusion, all interest rates, standard deviations, drifts, etc. will now be reported as numbers belonging to the unit interval $[0, 1]$ (rather than as percentages between 0 and 100).

In the author’s prior work on margin loan pricing in continuous time (Garivaltis 2019a-b), he derived the simple theoretical relationship

$$\text{Margin Loan Interest Rate}_t = \frac{\text{Broker Call Rate}_t}{2} + C,$$

where $C$ is a constant that is independent of the broker call rate and independent of the time $t$. This was done by assuming that the broker’s sole (representative) client is a continuous time Kelly gambler (cf. Luenberger 1998) who borrows cash over each differential time step $[t, t + dt]$ for the sake of leveraged betting on a single risk asset (say, the market index) whose price $S_t$ follows the geometric Brownian motion

$$dS_t := S_t(\mu_S dt + \sigma_S dW_t^S),$$

$$d(\log S_t) = (\mu_S - \sigma_S^2/2) dt + \sigma_S dW_t.$$

Here, we have used the symbol $dW^S(t)$ to denote the standard Brownian motion that drives the asset price; the drift and volatility are $\mu_S$ and $\sigma_S$, respectively. The corresponding Kelly bet (cf. Thorp 2006) for this market over the interval $[t, t + dt]$ amounts to the client betting the fraction

$$b(r_L) := \frac{\mu_S - r_L}{\sigma_S^2}$$

of his wealth on the stock, where $r_L$ denotes the continuously-compounded interest
rate charged by the broker for the duration \([t, t+dt]\). Thus, the instantaneous quantity of margin loans demanded per dollar of client equity (e.g. the \textit{instantaneous demand curve}) is given by the formula

\[
q(r_L) := b(r_L) - 1 = \left( \frac{\mu_S}{\sigma_S^2} - 1 \right) - \frac{1}{\sigma_S^2} r_L. \tag{57}
\]

Equivalently, the broker faces the inverse (instantaneous) demand curve

\[
r_L = (\mu_S - \sigma_S^2) - \sigma_S^2 q \tag{58}
\]

for the duration \([t, t + dt]\). On account of the fact that the broker has constant marginal cost (viz. the broker call rate), the corresponding monopoly midpoint price is

\[
\text{Margin Rate}_t = \frac{\text{Marginal Cost}_t + \text{Choke Price}}{2} = \frac{\text{Call Rate}_t}{2} + \frac{\mu_S - \sigma_S^2}{2} = \frac{\text{Call Rate}_t}{2} + \frac{1}{2} (\nu_S - \sigma_S^2/2), \tag{59}
\]

where the parameter \(\nu_S := \mu_S - \sigma_S^2/2\) represents the expected compound (logarithmic) growth rate of the market index (say, the S&P 500). Thus, our constant \(C\) is given by

\[
C := \frac{\nu_S}{2} - \frac{\sigma_S^2}{4}. \tag{60}
\]

Given the backdrop of our mean-reverting empirical model of the broker call rate, The theoretical pricing formula \((53)\) implies that the margin loan interest rates charged
by brokers must also follow an Ornstein-Uhlenbeck process. For, we have

\[
d(\text{Margin Rate}_t) = \frac{d(\text{Call Rate}_t)}{2} = -\frac{\theta}{2}(\text{Call Rate}_t - \mu) \, dt + \frac{\sigma}{2} \, dW_t. \tag{61}\]

Bearing in mind that \(\text{Call Rate}_t = 2(\text{Margin Rate}_t - C)\), we get the law of motion

\[
d(\text{Margin Rate}_t) = -\theta(\text{Margin Rate}_t - \mu/2 - C) \, dt + \frac{\sigma}{2} \, dW_t. \tag{62}\]

Thus, we conclude that the long-run average of the margin loan interest rate charged by stock brokers should be \(\mu/2 + C\), and that margin loan prices should exhibit the same level of mean reversion (\(\bar{\theta}\)) as the broker’s cost of funding. However, the random fluctuations in the margin loan interest rate should have half the magnitude of the corresponding movements in the broker call rate.

Following Garivaltis (2019b), if we use the stylized parameters \(\nu_S := 0.09, \sigma_S := 0.15\), and \(\mu_S := \nu_S + \sigma_S^2/2\) to represent the (annual) dynamics of the S&P 500 index, then we get \(C = 0.03938\). Thus, our hybrid empirical/theoretical model of the margin loan interest rate is

\[
d(\text{Margin Rate}_t) = -0.516(\text{Margin Rate}_t - 0.05909) \, dt + 0.01495 \, dW_t. \tag{63}\]

On account of the linear relationship \(b = (\mu_S - r_L)/\sigma_S^2\) between the margin loan interest rate and the bet size \(b\), it follows that the client’s quantity \(q = b - 1\) of margin loans per dollar of equity must also follow an Ornstein-Uhlenbeck process. A straightforward calculation shows that

\[
db_t = dq_t = -\bar{\theta} \left( q_t - \frac{\mu_S - \mu}{2\sigma_S^2} \right) \, dt - \frac{\sigma}{2\sigma_S^2} \, dW_t, \tag{64}\]
where the time \( t \) is measured in months and \( W_t \) is the standard Brownian motion that drives the broker call rate. Thus, the leverage ratio of the (representative) Kelly gambler reverts to its long-term mean of \((\mu_S - \bar{p})/(2\sigma_S^2)\) at the same rate \( \theta \) as the broker call rate and the margin loan interest rate. Given our empirical findings, we have the concrete (monthly) law of motion:

\[
\frac{db_t}{b_t} = -0.516(b_t - 2.0338) \, dt - 0.6644 \, dW_t. \tag{65}
\]

Thus, the long-term average leverage ratio of continuous time Kelly gamblers is \( \bar{b} := 2.0338 \), for an average quantity of \( \bar{q} := $1.0338 \) borrowed per dollar of client equity. The (stationary) standard deviation of the clients’ leverage ratios is

\[
\text{Std}(b_t) = \frac{\bar{\sigma}}{2\sigma_S^2 \sqrt{2\theta}} = 0.654. \tag{66}
\]

Figure (13) plots a 12-month simulation of the leverage ratios of Kelly gamblers, assuming an initial value of \( b_0 := 2 \).
4 Arbitrage Pricing of Call Loans

In this section, we use Merton’s (1974, 1992) no-arbitrage approach to corporate liability pricing to derive theoretical formulas for the broker call rate and the net interest margin that banks should earn on such loans. On that score, we let $r$ denote the risk-free rate of interest, and we let $R$ denote the broker call rate, where $\rho := R - r > 0$ is the corresponding risk premium. The broker himself charges his retail

“A fuller account would address the pledging of customers’ securities by broker-dealers to obtain loans from financial institutions.”

— Peter Fortune (2000), in the New England Economic Review
customers a margin loan interest rate of $\overline{R} > R$. We assume that the (representative)
brokerage client borrows $D$ dollars to finance the purchase of a single share of a
risky stock or index, whose initial price at time 0 is $S_0$. The client’s initial equity is $E_0 := S_0 - D > 0$. As usual, we assume that the asset price follows the geometric
Brownian motion

$$dS_t := S_t(\mu dt + \sigma dW_t), \quad (67)$$

where $\mu$ is the annual drift rate, $\sigma$ is the annual volatility, and $W_t$ is a standard
Brownian motion\(^2\). Interest is assumed to compound continuously over the loan term
$[0, T]$, so that the client’s accumulated margin loan (debit) balance at time $t$ is $De^{\overline{R}t}$.
Thus, his equity fluctuates according to the random process $E_t := S_t - De^{\overline{R}t}$.

If the broker was willing or able to continuously monitor the client’s account for
solvency, then there would be no credit risk, for, on account of the continuous sample
path of $(E_t)_{t \in [0, T]}$, the broker could liquidate the account the instant that $E_t = 0$ (or
some other threshold $E$). Thus, under continuous monitoring, there is certainly no
risk to the bank that funded part of the margin loan; in this case, the no-arbitrage
axiom dictates that $\overline{R} = r$. In order to have $\overline{R} > r$ in equilibrium, we must start with
a situation whereby it is possible for the retail client to default on his margin loan.
Thus, as in Fortune (2000) and Garivalitis (2019a), we assume that the broker does
not monitor the client’s account for solvency until some given maturity date, $T$.

However, if the broker is willing to maintain a dynamically precise short position
in the risk asset (cf. Fortune 2000 and Garivalitis 2019a), then it is possible, in the
sense of Black and Scholes (1973), to completely “eliminate risk” through continuous
trading in the underlying. In this happenstance, the no-arbitrage principle implies a
unique margin loan interest rate $\overline{R} > r$, but it fails to give us a characterization of

\(^2\) For the purposes of this section, we are using a fresh “namespace,” whereby the symbols
$\mu, \sigma, \rho, W_t, T$, etc. are divorced from what they stood for in the prequel.
the call money rate, since there is no actual risk to the bank that funded the margin loan. Thus, in order to generate risk premia in the call money market, we must make the twin assumptions:

1. The broker does not check the client’s portfolio for solvency until the maturity date, $T$.
2. The broker is not willing or able to hedge his own default risk.

In this environment, we now have the possibility of a “default cascade” whereby the client defaults on his margin loan at $T$, and this in turn causes the broker to default on his debt to the money market. Accordingly, we will assume that the broker borrows $d < D$ dollars on the money market for the sake of funding the $D$ dollar margin loan; the remaining $D - d$ dollars of the margin loan constitute the broker’s own equity. That is, we have the decomposition

\[
\text{Total Leveraged Portfolio Value} = \text{Client’s Equity} + \text{Broker’s Equity} + \text{Call Loan Balance}.
\]

Equivalently, this means that for $0 \leq t < T$, we have

\[
\text{Broker’s Equity}_t = S_t - E_t - de^{R_t} = De^{\bar{R}_t} - de^{R_t} \\
= \text{Broker’s Assets}_t - \text{Broker’s Liabilities}_t.
\]

Following Fortune (2000) and Garivalitis (2019a), we assume that the retail client will abandon his account at $T$ if $E_T \leq 0$, leaving the broker with collateral worth $S_T$. 

29
The propagation of margin loan risk in Black-Scholes markets

| Credit Event | Upshot |
|--------------|--------|
| $S_T \geq D e^{\bar{R} T}$ | No defaults |
| $d e^{\bar{R} T} \leq S_T < D e^{\bar{R} T}$ | Retail client defaults but broker does not |
| $S_T < d e^{\bar{R} T}$ | Retail client and broker both default |

Table 4: The three possible credit events faced by the call lender.

Thus, the broker’s assets at the end of the loan term amount to

$$\min(S_T, D e^{\bar{R} T}), \quad (70)$$

and the broker’s final equity is equal to

$$\min(S_T, D e^{\bar{R} T}) - d e^{\bar{R} T}. \quad (71)$$

If the broker’s final equity is $\leq 0$, then he himself will default on his debt to the money market, leaving his creditors with collateral in the amount of $\min(S_T, D e^{\bar{R} T})$.

Thus, the final payoff that accrues at $T$ to the bank that made the call loan is

$$\min\{\min(S_T, D e^{\bar{R} T}), d e^{\bar{R} T}\} = \min(S_T, d e^{\bar{R} T}), \quad (72)$$

where we have made use of the fact that $d < D$ and $\bar{R} < \bar{R}$. Table 4 summarizes the three possible credit events faced by the call lender.

Assuming that the bank’s call money was itself borrowed at the risk-free rate $r$, the bank’s final profit (loss) is

$$\pi_T := \min(S_T, d e^{\bar{R} T}) - d e^{r T}. \quad (73)$$
Making use of the identity \( \min(x, y) = x + y - \max(x, y) \), we have

\[
\pi_T = S_T + de^{RT} - \max(S_T, de^{RT}) - de^{rT} \\
= S_T - de^{rT} - [\max(S_T, de^{RT}) - de^{RT}] \\
= [S_T - de^{rT} - \max(S_T - K, 0)],
\]

(74)

where \( K := de^{RT} \). That is to say, the bank’s (random) profit \( \pi_T \) amounts to the final payoff of the following portfolio:

- Long one share of the stock

- Short \( d \) dollars at the risk-free rate of interest

- Short one European-style call option at a strike price of \( K := de^{RT} \).

Naturally, the bank can hedge its (net long) exposure to the underlying (e.g. the bank has \textit{de facto} written a covered call) by shorting a dynamically precise amount of the retail client’s portfolio. In order to prevent riskless arbitrage opportunities, the time-0 expected present value of the bank’s profit with respect to the equivalent martingale measure (\( Q \)) must be zero:

\[
0 = E_Q^Q[\pi_T] = S_0 - d - \text{BSCall}(S_0, 0, K, r, \sigma, T). \tag{75}
\]

Recalling the Black and Scholes (1973) formula

\[
\text{BSCall}(S_0, 0, K, r, \sigma, T) = S_0 N(d_1) - Ke^{-rT} N(d_2), \tag{76}
\]
where
\[
d_1 := \log\left(\frac{S_0}{K}\right) + (r + \sigma^2/2)T \quad \sigma \sqrt{T}
\]
and
\[
d_2 := d_1 - \sigma \sqrt{T},
\]
and simplifying, we get the following equation characterizing the broker call rate:
\[
d/S_0 = \frac{N(-d_1) e^{\rho T}}{1 - N(d_2) e^{\rho T}}
\]
where \(\rho := R - r\) is the risk premium for call money,
\[
-d_1 = \log\left(\frac{d}{S_0}\right) + (\rho - \sigma^2/2)T \quad \sigma \sqrt{T}
\]
and the ratio \(d/S_0\) represents the percentage of the portfolio that has been financed by call money. As usual, \(N(\bullet)\) denotes the cumulative normal distribution function.

Note that the broker call rate \(R\) does not depend on the drift \(\mu\) or on the margin loan interest rate \(\bar{R}\) that the broker charges its clients. The characterization \((79)\) of \(R\) is not particular to the numerical levels of \(d\) and \(S_0\); it only depends on their ratio \(d/S_0\). Similarly, the numbers \(r\) and \(\bar{R}\) only matter to \((79)\) in so far as their difference \(\rho := R - r\) is featured prominently. That is to say (cf. Merton 1974 and Merton 1992), the risk premium for call money depends only on the following credit characteristics:

- \(T\) (the loan term);
- \(d/S_0\) (the loan-to-value ratio);
- \(\sigma\) (the volatility of the collateral).

The bank’s net exposure to the underlying in state \((S_t, t)\) is equal to (cf. Wilmott
Figure 14: The implied loan-to-value ratios ($d/S_0$) and hedge ratios ($\Delta$) for different values of the broker call rate ($r := 2.088\%, T := 90/365, \sigma := 40\%$).

1998):

$$\Delta(S,t) := \frac{\partial}{\partial S}[S - d e^{rt} - \text{BSCall}(S, t, K, r, \sigma, T)] = 1 - N(d_1) = N(-d_1). \quad (81)$$

Thus, $\Delta = N(-d_1)$ represents the (dynamic) percentage of the retail client’s portfolio that must be sold short by banks in order to hedge their counterparty risk.

Figure 14 plots the implied loan-to-value ratio $d/S_0$ and the implied short position $\Delta = N(-d_1)$ for different values $R$ of the broker call rate. Here, we have assumed a risk-free rate of $r := 2.088\%$ (which is the current 5-year U.S. Treasury yield as of this writing), a 90-day loan term ($T := 90/365$), and a conservative value of $\sigma := 40\%$ annual stock market volatility.

Thus, we have obtained the following (“puzzling”) conclusion: even under the conservative assumptions of a long (90-day) loan term and very high (40%) annual
stock market volatility, the no-arbitrage axiom implies that 72.3% (!!) of the value of all U.S. leveraged portfolios has been financed by call money. This means that the sum total of broker and client equity must amount to only 27.7% of the value of all leveraged portfolios. These figures contradict the well-known legal constraint (e.g. U.S. Regulation-T) on retail margin debt:

\[ d/S_0 \leq D/S_0 \leq 0.5 \]

To avoid this logical contradiction, we must admit the possibility that the banks and financial institutions that lend call money to stock brokers in the United States may be earning substantial arbitrage profits on the spread over the risk-free rate.

Note well that varying the term of the call loan is of no great help in resolving the puzzle; indeed, Figure 15 plots the implied maturities \( T \) that would rationalize different values \( R \) of the broker call rate, assuming the parameters \( r := 2.088\% \), \( \sigma := 40\% \), and \( d/S_0 := 50\% \). For the currently observed call rate of 4.25%, we get an implied loan term of 1.75 years and an implied delta in the amount of 6.6% of the retail client’s portfolio.

5 Summary and Conclusions

Inspired by the author’s prior theoretical work on margin loan pricing (Garivaldis 2019a-b), this paper described and analyzed a collection of 1,367 monthly observations of the U.S. broker call money rate (1857:01 through 1970:11) supplied by the Federal Reserve Bank of St. Louis (FRED). Our estimated AR(1) specification (and corresponding Ornstein-Uhlenbeck model) indicates that for every 100 basis points of deviation from its long-term average of 3.943%, the (continuously-compounded)
broker call rate will revert to the mean at an expected rate of 40.3 basis points per month, but this reversion is disturbed by monthly innovations whose root-mean-squared magnitude is 2.362%. Buoyed by the fact that Bankrate.com reports the two most recent observations of the broker call money rate (4.25% as of this writing), we constructed an AR(2) model that reduced the monthly root-mean-squared prediction error (in-sample) by 6.5 basis points, to 2.297%.

We proceeded to reconcile this empirical law of motion with following theoretical relationship (Garivaltis 2019a), based on instantaneous monopoly pricing of margin loans to Kelly gamblers:

\[
\text{Margin Loan Interest Rate}_t = \frac{1}{2}(\text{Broker Call Rate}_t) + \frac{1}{2}(\nu_S - \sigma_S^2/2),
\]

where \( \nu_S \) denotes the long-run compound annual (logarithmic) growth rate of the stock market, and \( \sigma_S \) is its annual volatility. Under this arrangement, only half of the random movements in the broker call rate get passed on to retail consumers. Assuming the stylized parameter values \( \nu_S := 0.09 \) and \( \sigma_S := 0.15 \) for the S&P 500
index, we obtained a hybrid empirical/theoretical law of motion for the margin loan interest rate charged by stock brokers:

\[
d(Margin \text{ Rate}_t) = -0.516(Margin \text{ Rate}_t - 5.909) + 1.495 \, dW_t. \tag{84}
\]

Thus, the margin loan interest rate will display the same rate of (continuous) mean-reversion as does the broker call rate; the unanticipated instantaneous changes in the margin rate \( = 1.495 \, dW_t \) will be half the size of the corresponding movements in the broker call rate. We then derived a stochastic differential equation that governs the (monthly) leverage ratios \( (b_t) \) of continuous time Kelly gamblers:

\[
 db_t = -0.516(b_t - 2.0338) \, dt - 0.6644 \, dW_t. \tag{85}
\]

Hence, our empirical finding is that the long-term average interest rate on margin loans should be 5.9%, and that the leverage ratios of sophisticated brokerage clients should oscillate randomly about an equilibrium level of 2.03 : 1.

Finally, we used Merton’s (1974) no-arbitrage method to uniquely characterize the correct risk premium \( \rho := \bar{R} - r \) that commercial banks should earn on their loans to stock brokers. We assumed that brokers loan money to retail clients at a marked-up rate of \( \bar{R} > R \); to generate risk premia in the market for call money, we had to assume that stock brokers are not willing or able to short their customers’ portfolios for the sake of hedging the default risk.

Thus, we modeled a situation whereby commercial banks are exposed to the risk of a cascaded default, meaning that the retail client defaults on his margin loan and the brokerage in turn defaults on its debt to the money market. The commercial
bank can hedge this risk by shorting the dynamically precise fraction

$$\Delta_t = N\left(\frac{\log(d/S_t) + (\rho - \sigma^2/2)(T-t)}{\sigma\sqrt{T-t}}\right),$$  \hspace{1cm} (86)$$

of the retail client’s portfolio at time \(t\), where \(T\) is the maturity date of the call loan, \(\rho\) is the risk premium for call money, \(d/S_t\) is the percentage of the client’s portfolio that is financed with call money (as opposed to broker equity and client equity), and \(\sigma\) is the annual volatility of the collateral.

Under very conservative assumptions (40% annual volatility and a 90-day loan term), we concluded that call lenders’ current level of exposure to the stock market amounts to \(\Delta = 4.4\%\) of the value of all leveraged portfolios in the United States. Comparing the current broker call rate of 4.25% with the prevailing U.S. Treasury yields, we found that the implied loan-to-value ratio is north of 70%. This is absurd on account of U.S. Regulation-T, which caps the loan-to-value ratios of retail margin borrowers at 50%. In order to alleviate this apparent contradiction, we must live with the possibility that U.S. banks who deal in the market for call money could in fact be earning substantial arbitrage profits on the spread of the broker call rate over the risk-free rate.
