ABSTRACT
With the hundreds of merging binary black hole (BH) signals expected to be detected by LIGO/Virgo, LISA and other instruments in the next few years, the modeling of astrophysical channels that lead to the formation of compact-object binaries has become of fundamental importance. In this paper, we carry out a systematic statistical study of quadruple BHs consisting of two binaries in orbit around their center of mass, by means of high-precision direct \(N\)-body simulations including Post-Newtonian (PN) terms up to 2.5PN order. We found that most merging systems have high initial inclinations and the distributions peak at \(\sim 90^\circ\) as for triples, but with a more prominent broad distribution tail. We show that BHs merging through this channel have a significant eccentricity in the LIGO band, typically much larger than BHs merging in isolated binaries and in binaries ejected from star clusters, but comparable to that of merging binaries formed via the GW capture scenario in clusters, mergers in hierarchical triples, or BH binaries orbiting intermediate-mass black holes in star clusters. We show that the merger fraction can be up to \(\sim 5–10\times\) higher for quadruples than for triples. Thus even if the number of quadruples is 20%–25% of the number of triples, the quadruple scenario can represent an important contribution to the events observed by LIGO/VIRGO.

Key words: Galaxy: kinematics and dynamics – stars: black holes – stars: kinematics and dynamics – galaxies: star clusters: general

1 INTRODUCTION
The LIGO-Virgo collaboration has recently released a catalogue of compact object mergers due to gravitational wave (GW) emission, comprised of ten merging black hole (BH) binaries and one merging neutron (NS) binary (The LIGO Scientific Collaboration & the Virgo Collaboration 2018). As the detector sensitivity is improved, hundreds of merging binary signals are expected to be detected in the next few years, and the modeling of astrophysical channels that lead to the formation of compact-object binaries has become of fundamental importance.

Several astrophysical channels have been proposed leading to merging compact objects. Possibilities include isolated binary evolution through a common envelope phase (Belczynski et al. 2016; Giacobbo & Mapelli 2018), envelope expansion and fallback (Tagawa et al. 2018) or chemically homogeneous evolution (Mandel & de Mink 2016; Marchant et al. 2016), Lidov-Kozai (LK) mergers of binaries in galactic nuclei (Antonini & Perets 2012; Petrovich & Antonini 2017; Hamers et al. 2018; Hoang et al. 2018; Fragione et al. 2018; Grishin et al. 2018) and in stellar triple systems (Antonini et al. 2017; Silsbee & Tremaine 2017; Arca-Sedda et al. 2018; Liu & Lai 2018), GW capture events in galactic nuclei (O’Leary et al. 2009; Rasskazov & Kocsis 2019), mergers in active galactic nuclei (AGN) accretion disks (Bartos et al. 2017; Stone et al. 2017), mergers in dark matter halos (Bird et al. 2016; Sasaki et al. 2016), and mergers in star clusters (Portegies Zwart & McMillan 2000; O’Leary et al. 2006; Askar et al. 2017; Banerjee et al. 2018; Choksi et al. 2018; Fragione & Kocsis 2018; Rastello et al. 2018; Rodriguez et al. 2018). While typically each model accounts for roughly the same rate (\(\sim 5–10\times\) Gpc\(^{-3}\) yr\(^{-1}\)), with the possible exception of the isolated binary case which predicts possibly much higher rates), the statistical contribution of different astrophysical channels can be hopefully disentangled using the spin, mass, eccentricity and redshift distributions (see e.g. O’Leary et al. 2016; Gondán et al. 2018; Samsing et al. 2018a; Zevin et al. 2019).

Bound stellar multiples are not rare. In particular, for massive stars which are progenitors of NSs and BHs, observations have shown that more than \(\sim 50\%\) and \(\sim 15\%\) have at least one or two stellar companions, respectively (Duquennoy & Mayor 1991; Raghavan et al. 2010; Sana et al. 2013; Tokovinin 2014a,b; Dunstall et al. 2015; Sana et al. 2018; Grishin et al. 2018) and in stellar triple systems (Antonini et al. 2017; Silsbee & Tremaine 2017; Arca-Sedda et al. 2018; Liu & Lai 2018), GW capture events in galactic nuclei (O’Leary et al. 2009; Rasskazov & Kocsis 2019), mergers in active galactic nuclei (AGN) accretion disks (Bartos et al. 2017; Stone et al. 2017), mergers in dark matter halos (Bird et al. 2016; Sasaki et al. 2016), and mergers in star clusters (Portegies Zwart & McMillan 2000; O’Leary et al. 2006; Askar et al. 2017; Banerjee et al. 2018; Choksi et al. 2018; Fragione & Kocsis 2018; Rastello et al. 2018; Rodriguez et al. 2018). While typically each model accounts for roughly the same rate (\(\sim 5–10\times\) Gpc\(^{-3}\) yr\(^{-1}\)), with the possible exception of the isolated binary case which predicts possibly much higher rates), the statistical contribution of different astrophysical channels can be hopefully disentangled using the spin, mass, eccentricity and redshift distributions (see e.g. O’Leary et al. 2016; Gondán et al. 2018; Samsing et al. 2018a; Zevin et al. 2019).

Bound stellar multiples are not rare. In particular, for massive stars which are progenitors of NSs and BHs, observations have shown that more than \(\sim 50\%\) and \(\sim 15\%\) have at least one or two stellar companions, respectively (Duquennoy & Mayor 1991; Raghavan et al. 2010; Sana et al. 2013; Tokovinin 2014a,b; Dunstall et al. 2015; Sana et al. 2018; Grishin et al. 2018) and in stellar triple systems (Antonini et al. 2017; Silsbee & Tremaine 2017; Arca-Sedda et al. 2018; Liu & Lai 2018), GW capture events in galactic nuclei (O’Leary et al. 2009; Rasskazov & Kocsis 2019), mergers in active galactic nuclei (AGN) accretion disks (Bartos et al. 2017; Stone et al. 2017), mergers in dark matter halos (Bird et al. 2016; Sasaki et al. 2016), and mergers in star clusters (Portegies Zwart & McMillan 2000; O’Leary et al. 2006; Askar et al. 2017; Banerjee et al. 2018; Choksi et al. 2018; Fragione & Kocsis 2018; Rastello et al. 2018; Rodriguez et al. 2018). While typically each model accounts for roughly the same rate (\(\sim 5–10\times\) Gpc\(^{-3}\) yr\(^{-1}\)), with the possible exception of the isolated binary case which predicts possibly much higher rates), the statistical contribution of different astrophysical channels can be hopefully disentangled using the spin, mass, eccentricity and redshift distributions (see e.g. O’Leary et al. 2016; Gondán et al. 2018; Samsing et al. 2018a; Zevin et al. 2019).

Bound stellar multiples are not rare. In particular, for massive stars which are progenitors of NSs and BHs, observations have shown that more than \(\sim 50\%\) and \(\sim 15\%\) have at least one or two stellar companions, respectively (Duquennoy & Mayor 1991; Raghavan et al. 2010; Sana et al. 2013; Tokovinin 2014a,b; Dunstall et al. 2015; Sana et al. 2018; Grishin et al. 2018) and in stellar triple systems (Antonini et al. 2017; Silsbee & Tremaine 2017; Arca-Sedda et al. 2018; Liu & Lai 2018), GW capture events in galactic nuclei (O’Leary et al. 2009; Rasskazov & Kocsis 2019), mergers in active galactic nuclei (AGN) accretion disks (Bartos et al. 2017; Stone et al. 2017), mergers in dark matter halos (Bird et al. 2016; Sasaki et al. 2016), and mergers in star clusters (Portegies Zwart & McMillan 2000; O’Leary et al. 2006; Askar et al. 2017; Banerjee et al. 2018; Choksi et al. 2018; Fragione & Kocsis 2018; Rastello et al. 2018; Rodriguez et al. 2018). While typically each model accounts for roughly the same rate (\(\sim 5–10\times\) Gpc\(^{-3}\) yr\(^{-1}\)), with the possible exception of the isolated binary case which predicts possibly much higher rates), the statistical contribution of different astrophysical channels can be hopefully disentangled using the spin, mass, eccentricity and redshift distributions (see e.g. O’Leary et al. 2016; Gondán et al. 2018; Samsing et al. 2018a; Zevin et al. 2019).
2 G. Fragione, B. Kocsis

2017; Jiménez-Esteban et al. 2019). Most previous dynamical studies on bound multiples have focused on determining the BH merger rate from isolated bound triples or triple BHs in globular clusters (Wen 2003; Antonini et al. 2016, 2017; Silsbee & Tremaine 2017; Arca-Sedda et al. 2018). Quadruple systems are also observed. Riddle et al. (2015) found a ∼ 4% abundance of 2+2 quadruples. Compared to triple systems, quadruples have one additional degree of freedom and excursions to very high eccentricity can take place over a much larger fraction of the parameter space (Pejcha et al. 2013).

The dynamics of 2+2 quadruple systems has been under scrutiny to investigate a number of astrophysical phenomena. Tokovinin (2018) analysed 2+2 systems and found that they may be formed either sequentially by disk fragmentation with subsequent accretion and migration or by a hierarchical fragmentation cascade of a rotating cloud. Fang et al. (2017) and Hamers (2018) studied 2+2 quadruple dynamics in the context of white dwarf-white dwarf mergers and collisions connected to Type Ia supernovae. Seto (2018) investigated the orbital synchronization of 2+2 quadruples and their implications for gravitational waves. Arca-Sedda et al. (2018) and Zevin et al. (2019) examined binary-binary scattering events, which may lead to eccentric BH mergers. Recently, Liu & Lai (2019) have discussed the possibility that the richer dynamics of quadruples can lead to a merger fraction ∼ 10 times higher than that of triple systems, thus highlighting the relevance of this channel.

In this paper, we study for the first time the dynamical evolution of 2+2 quadruple BHs by means of direct high-precision N-body simulations, including Post-Newtonian (PN) terms up to 2.5PN order. In our calculations, we consider a power-law mass spectrum for the BHs, different maximum extensions of the quadruple and different distributions of the inner and outer semi-major axes and eccentricities. We quantify how the probability of merger depends on the initial conditions and determine the parameter distribution of merging systems relative to the initial distributions.

The paper is organized as follows. In Section 2, we discuss the relevant timescales of the considered systems. In Section 3, we present our numerical methods to determine the rate of BH mergers in quadruples, and discuss the parameters of merging systems. Finally, in Section 4, we discuss the implications and draw conclusions.

2 LIDOVA KOZAI MECHANISM IN QUADRUPLES

Figure 1 illustrates the system considered in this paper. The system consists of two inner binaries with masses \((m_1, m_2)\) and \((m_3, m_4)\), respectively, whose center of masses orbit around the 4-body system’s center of mass, denoted as the outer binary. The semimajor axes and eccentricities of the inner binaries are denoted by \(a_{12}, e_{12}\) and \(a_{34}, e_{34}\), respectively, and of the outer orbit by \(a_{\text{out}}\) and \(e_{\text{out}}\).

In the case of a triple system made up of an inner binary that is orbited by a companion, the inner eccentricity and inclination oscillate due to the quadrupole moment of the tidal potential of the third body via the LK mechanism whenever the initial mutual orbital inclination is between \(i_0 \sim 40^\circ-140^\circ\) (Lidov 1962; Kozai 1962). The semimajor axis is approximately fixed during these oscillation cycles. At the secular quadrupole order of approximation, these oscillations occur on a timescale (Naoz 2016)

\[
T_{\text{LK}} = \frac{8}{15 \pi} \frac{\dot{m}_{\text{tot}} P_{3b}^2}{m_{3b} P_{\text{in}}} \left(1 - \frac{e_{3b}^2}{3} \right)^{3/2},
\]

where \(P_{\text{in}}\) and \(P_{3b}\) are the orbital periods of the inner and outer binary, respectively, \(m_{3b}\) is the mass of the perturber, and \(m_{\text{tot}}\) is the total mass of the triple system. At the quadrupole order of approximation, the maximal eccentricity of the inner binary due to the LK mechanism depends on the initial mutual inclination

\[
e_{\text{in}}^{\text{max}} = \sqrt{1 - \frac{5}{3} \cos i_0^2}.
\]

As \(i_0\) approaches ∼ 90°, the inner binary eccentricity approaches almost unity. In the case of a compact-object binary, the large eccentricity makes its GW merger time shorter since it dissipates energy more efficiently at the pericentre (e.g., see Antognini 2015; Naoz 2016). Nevertheless, LK cycles can be suppressed by additional sources of precession, such as tidal bulges or general relativistic precession, which operate on a typical timescale of (Naoz 2016)

\[
T_{\text{GR}} = \frac{a_{\text{in}}^3}{3G^{3/2} (m_{\text{in},1} + m_{\text{in},2})^{3/2}}\left(1 - \frac{e_{\text{in}}^2}{3}\right)^{3/2}.
\]

If \(T_{\text{GR}} < T_{\text{LK}}\), the LK oscillations of the \((e_{\text{in}}, i)\) orbital elements are damped by relativistic effects (Naoz et al. 2013). If the octupole corrections are taken into account, the eccentricity excitation becomes more prominent. In the case of the outer orbit is eccentric, the inner eccentricity can reach almost unity even if the initial inclination is outside of the \(i_0 \sim 40^\circ-140^\circ\) Kozai-Lidov range (Naoz et al. 2013; Li et al. 2014).

In the case the third companion is itself a binary star, as assumed in this paper, each binary acts as a distant perturber inducing LK cycles on the other binary. The evolution
of such 2+2 quadruple systems differs from a combination of two uncoupled three-body LK processes. Pejcha et al. (2013) showed that the binaries can experience coherent eccentricity oscillations and excursions to very high eccentricity that take place over a much larger fraction of the parameter space compared to triple systems. Hamers & Lai (2017) showed that the reason for this behaviour is that the second binary can induce nodal precession to the outer (2+2) orbit, which can cause a secular resonance if it happens on a timescale comparable to the LK timescale, and make the first binary merge. With respect to the first inner binary, the strength of this effect is parametrised by the dimensionless parameter (Hamers & Lai 2017)

$$\eta = \frac{3}{4} \cos I_2 \left( \frac{a_{12}}{a_{34}} \right)^{3/2} \left( \frac{m_1 + m_2}{m_3 + m_4} \right)^{3/2},$$  \hspace{1cm} (4)$$

where $\cos I_2$ is the inclination of the orbital plane of the second inner binary compared to the outer orbital plane. When $\eta \sim 1$, the timescale of the induced nodal precession and of the LK mechanism of the first binary are comparable and the resonance has its maximum effect.

Liu & Lai (2019) have recently discussed that dynamically induced BH mergers in quadruple systems may be an important channel of producing BH mergers observed by LIGO/VIRGO due to the richer dynamics of 2+2 systems.

### 3 N-BODY SIMULATIONS: BLACK HOLE MERGERS

The BH quadruples in our simulations are initialized as follows. In total, we consider seven different models with different distributions of quadruple parameters (see Tab. 1) to explore the role of the relevant quadruple parameters.

In our models, we sample the masses of the BHs from

$$\frac{dN}{dm} \propto M^{-\beta},$$  \hspace{1cm} (5)$$

in the mass range 5 M_\odot-100 M_\odot (Hoang et al. 2018). To check how the results depend on the slope of the BH mass function, we run models with $\beta = 1, 2, 3, 4$ (O’Leary et al. 2016). The inner ($a_{12}, a_{34}$) and outer ($a_{out}$) semi-major axes are drawn either from a uniform distribution ($f(a) \propto const$) or a log-uniform ($f(a) \propto 1/a$) distribution. The minimum inner semimajor axis is 1 AU. We also consider two different maximum outer semimajor axis $a_{out}^{max}$ for the quadruples (1000 AU or 3000 AU). The inner ($e_{12}, e_{34}$) and outer ($e_{out}$) eccentricities are sampled from a uniform ($f(e) \propto const$) or thermal ($f(e) \propto e$) distribution. The initial mutual inclination $i_0$ between the inner and outer orbit is sampled from an isotropic distribution (i.e. uniform in $\cos i$). The other relevant angles are drawn randomly.

After sampling the relevant parameters, we check that the initial configuration satisfies the stability criterion of hierarchical triples of Mardling & Aarseth (2001), which is assumed to be valid for quadruple systems if the third companion is appropriately replaced by a binary system

$$\frac{R_p}{a_{in}} \geq 2.8 \left(1 + \frac{m_{out}}{m_{in,1} + m_{in,2}}\right)^{1 + e_{out}} \frac{1 + e_{out}}{\sqrt{1 - e_{out}}}^{2/5}.$$  \hspace{1cm} (6)$$

In the previous equation, $m_{in,1}$ and $m_{in,2}$ represent the masses of the inner binary, $m_{out}$ the total mass of the binary companion and $R_p = a_{in}(1 - e_{out})$ is the pericentre distance of the outer orbit.

Given the above set of initial parameters, we integrate

| Name | $a_{out}^{max}$ (AU) | $\beta$ | $f(a)$ | $f(e)$ | $f_{max}$ |
|------|---------------------|--------|--------|--------|----------|
| A1   | 1000                | 1      | uniform | uniform | 0.29     |
| A2   | 1000                | 2      | uniform | uniform | 0.29     |
| A3   | 1000                | 3      | uniform | uniform | 0.25     |
| A4   | 1000                | 4      | uniform | uniform | 0.24     |
| B1   | 3000                | 1      | uniform | uniform | 0.26     |
| B2   | 1000                | 1      | log-uniform | uniform | 0.28     |
| B3   | 1000                | 1      | uniform | thermal | 0.35     |

Table 1. Models: name, maximum outer semi-major axis ($a_{out}^{max}$), slope of the BH mass function ($\beta$), semi-major axis distribution ($f(a)$), eccentricity distribution ($f(e)$), merger fraction ($f_{max}$).
the system of differential equations of motion of the 4-bodies
\[
\ddot{r}_i = -G \sum_{j \neq i} \frac{m_j (r_i - r_j)}{|r_i - r_j|^3},
\]
with \(i = 1, 2, 3, 4\), by means of the ARCHAIN code (Mikkola & Merritt 2006, 2008), a fully regularized code able to model the evolution of binaries of arbitrary mass ratios and eccentricities with high accuracy and that includes PN corrections up to order PN2.5. We performed 1000 simulations for each model in Tab. 1. We fix the maximum integration time as 
\[
T = \min (10^3 \times \max (T_{\text{LK},12}, T_{\text{LK},34}), 10 \text{ Gyr}),
\]
where \(T_{\text{LK},12}\) and \(T_{\text{LK},34}\) are the LK timescales of the first \((m_1, m_2)\) and second \((m_3, m_4)\) inner binary, respectively.

Figure 2 shows the results of a four-body integration of one representative quadruple system with masses \(m_1 = 5.4 \text{ M}_\odot, m_2 = 7.5 \text{ M}_\odot, m_3 = 9.1 \text{ M}_\odot, m_4 = 9.4 \text{ M}_\odot\). The first two BHs start with an orbital inclination of \(i_{12} = 102.9^\circ\) with respect to the quadruple orbital plane, semi-major axis \(a_{12} = 8.45\) AU, and eccentricity \(e_{12} = 0.8\). As a consequence of the efficient dissipation at high eccentricities pumped up by the LK effect (bottom panel), the BHs merge after \(\sim 1.5 \times 10^7\) yr. We note that binaries may enter the non-secular regime during the maximum of an LK oscillation and the secular equation of motions are a poor description of the quadruple dynamics. In this regime, the inner binary BHs can be driven to a merger before general relativistic effects suppress the LK oscillations.

We now describe the key physical properties of the BHs that merge in our models.

### 3.1 Inclination distribution

In Figure 3, we show the probability distribution function (PDF) of the initial inclination between the inner binary orbit and the outer orbit of the BH binaries in quadruples that lead to a merger (top panel) and do not lead to a merger (bottom panel), for different slopes \(\beta\) of the BH mass function (Models A). Figure 3 shows that the majority of the merging systems have initially high inclinations and that the distributions peak at \(\sim 90^\circ\). However, binaries in quadruples can experience coherent eccentricity oscillations and excursions to very high eccentricity over a much larger...
fraction of the parameter space compared to triple systems (Pejcha et al. 2013) and possible resonances between the nodal precessions and the LK oscillations can arise (Hamers & Lai 2017). As a consequence, the inclination distribution of merging BHs in our four-body simulations shows broader tails compared to the BH mergers in triples (see Figure 2 in Antonini et al. 2017).

3.2 Masses

To examine the expected total mass $m_{\text{tot}}$ and the chirp mass

$$M_{\text{chirp}} = m_{\text{tot}} \frac{q^{3/5}}{(1 + q)^{6/5}}$$

of the merging binaries in quadruples ($q = m_1/m_2$, with $m_1 > m_2$, is the mass ratio of merging BHs), we have run models with different values of the slope of the BH mass function.

Figure 4 reports the distribution of mass ratios of BH binaries in quadruples (top) and of BH binaries in quadruples (bottom) that lead to a merger for different $\beta$’s. We find that the distribution of mass ratios of merging BH binaries maps the overall distribution for all the values of $\beta$. Steeper mass functions predict mergers of BHs with similar masses, while shallower mass functions allow a broader distribution with mass ratio down to $q \sim 0.05$. The mass ratio distribution of merging systems follows the prior mass ratio distribution of randomly drawing two objects from the BH mass function.

Figure 5 reports the total mass distribution of BH binaries in quadruples, total mass of BH binaries that lead to a merger, and chirp mass for $\beta = 1$ (top-left), $\beta = 2$ (top-right), $\beta = 3$ (bottom-left), $\beta = 4$ (bottom-right).

The distribution of chirp masses also depends on $\beta$, but
3.3 Orbital semi-major axis and eccentricity

Figure 6 illustrates the distributions of orbital elements of the BH binaries in quadruples that lead to a merger for Model B.

In the top panel, we illustrate the distributions of inner (left) and outer (right) semi-major axes of merging binaries. The shape of the $a_{\text{in}}$ and $a_{\text{out}}$ distributions are mainly set by the initial distribution of semi-major axes and by the maximum extent of the quadruple $a_{\text{out}}^{\text{max}}$. In the case of Model A1 ($a_{\text{out}}^{\text{max}} = 1000$ AU and $f(\epsilon)$ uniform), the distribution of inner semi-major axes is peaked at $\sim 50$ AU and extends up to $\sim 200$ AU. The distribution shifts to larger values with a peak at 200 AU in Model B2, where the initial maximum semi-major axes was set to 3000 AU, while it is peaked at $\sim 15$ AU in Model B2, where the initial semi-major axes are drawn from a log-uniform distribution. A similar trend is present in the distributions of outer semi-major axis, which are peaked at $\sim 900$ AU, 2500 AU, 100 AU for Model A1, Model B1 and Model B2, respectively.

The adopted distribution of initial eccentricities, i.e. either uniform (Model A1) or thermal (Model B3), does not affect the distributions of inner and outer semi-major axis of merging systems.

In the bottom panel of Figure 6, we plot the distribution of the ratio of the outer pericentre to the inner semi-major axis (left) and the distribution of the ratio of the outer pericentre to the inner apocentre (right) for merging systems. Both distributions are almost independent of the initial distribution of orbital semi-major axes and eccentricities. We find that the distributions peak at $a_{\text{out}}(1-e_{\text{out}})/a_{\text{in}} \sim 10$ and $a_{\text{out}}(1-e_{\text{out}})/[a_{\text{in}}(1+e_{\text{in}})] \sim 5$ for merging binaries in quadruple systems universally for all of our models.

3.4 Eccentricity in the LIGO band

Figure 7 shows the distribution of eccentricities at the moment the peak GW frequency of the BH binaries enter the
Figure 7: Distribution of eccentricities at the moment the BH binaries enter the LIGO frequency band (10 Hz) for mergers produced by quadruples. Left panel: Model A; right panel: Models A1 and B (see Tab. 1). The vertical line shows the minimum $e_{10Hz} = 0.081$ where LIGO/VIRGO/KAGRA network may distinguish eccentric sources from circular sources (Gondán & Kocsis 2019). A significant fraction of binaries formed in quadruples have a significant eccentricity in the LIGO band.

\begin{equation}
    f_{GW} = \frac{\sqrt{G(m_1 + m_2)}}{\pi} \frac{(1 + e_{in})^{1.1954}}{a_{in}(1 - e_{in})^{1.5}}.
\end{equation}

Figure 7 shows that binaries formed in quadruples have larger eccentricities than those formed through many other channels, particularly mergers in isolated binary evolution and in SBHB ejected from star clusters (Fragione & Kocsis 2018; Giacobbo & Mapelli 2018; Rodriguez et al. 2018). However, mergers that follow from the GW capture scenario in clusters (Zevin et al. 2019) and galactic nuclei (O’Leary et al. 2009; Gondán et al. 2018; Rasskazov & Kocsis 2019), from resonant binary-single scattering in clusters (Samšing et al. 2018b), from hierarchical triples (Antonini et al. 2017), and from BH binaries orbiting intermediate-mass black holes in star clusters (Fragione & Bromberg in prep.) also present a similar peak at high eccentricities. We note that the high eccentricities we find in the binaries that merge in our simulations may imply that a fraction of these binaries could emit their maximum power at higher frequencies, possibly in the range of LISA. However, binaries that enter the LIGO band with high eccentricities ($\gtrsim 10^{-3}$) could be harder to detect with instruments like LISA (Chen & Amaro-Seoane 2017). Nevertheless, Randall & Xianyu (2019) and Hoang et al. (2019) have proposed that LK oscillations of binary BHs in a triple configuration have the potential to be observed by LISA. In the quadruple case, both the inner BH binaries can enter the LISA frequency band and produce observable eccentricity variations if their respective LK cycles happen to have similar duration.

3.5 Merger times

Figure 8 shows the merger time cumulative distribution functions (CDFs) of BH binaries in quadruples that lead to merger for Model A and Model B. The CDF function depends both on the maximum extent of the quadruple $a_{\text{out}}$ and on the initial distribution of semi-major axes, but it does not depend on the assumed slope of the BH mass function nor on the initial distribution of eccentricities. Larger $a_{\text{out}}$ imply a larger merger timescale. In Model A ($a_{\text{out}} = 1000$ AU), we find that $\sim 50\%$ of the mergers happen within $\sim 10^7$ yr, while in Model B1 ($a_{\text{out}} = 3000$ AU) within $\sim 10^6$ yr. In Model B2, where we sample the initial semi-major axes from a log-uniform distribution, $\sim 50\%$ of the BHs merge within $\sim 10^6$ yr.
4 DISCUSSION AND CONCLUSIONS

In this paper, we have studied the dynamical evolution of a bound 2+2 type quadruple BH to estimate if this channel can contribute to the observed rate of BHs mergers. As found in Liu & Lai (2019), quadruples have one additional degree of freedom and a richer dynamics, which can enhance the merger fraction.

We carried out a systematic statistical study of these systems by means of high-precision direct $N$-body simulations including Post-Newtonian (PN) terms up to 2.5PN order. We ran a series of simulations sampling a power-law mass spectrum for the BHs, different maximum extensions of the quadruple and different distributions of the inner and outer semi-major axes and eccentricities (Table 1).

- We found that the majority of the merging systems have high initial inclinations and that the distributions peak at $\sim 90^\circ$, as for triples, but with a broader distribution tail.
- We have also shown that the mass distribution of merging BH binaries simply follows the assumed prior distribution, thus there is no significant enhancement of the merger probability as a function of total mass, chirp mass, or mass ratio. The slope of the BH mass function affects the total mass distribution and the chirp mass distribution: the steeper the mass function, the smaller the average $m_{\text{tot}}$ and $M_{\text{chirp}}$. Specifically, $\sim 90\%$ of the mergers have total mass $\lesssim 50 M_\odot$, $\lesssim 30 M_\odot$ for $\beta = 2$, $\beta = 3$, $\beta = 4$, respectively, assuming that the BH mass function extends to $100 M_\odot$.
- The shape of the inner and outer semi-major axes distributions of merging systems, as well as the typical merging timescale, are mainly set by the initial distribution of semi-major axes and by the maximum extent of the quadruple $a_{\text{out}}^{\text{max}}$. The initial eccentricity distribution of the inner binaries does not play a significant role. We find that the distributions peak at $a_{\text{out}}(1 - e_{\text{out}})/a_{\text{in}} \sim 10$ and $a_{\text{out}}(1 - e_{\text{out}})/[a_{\text{in}}(1 + e_{\text{in}})] \sim 5$ for merging binaries in quadruple systems universally for all of our models.
- Finally, we have computed the eccentricity in the LIGO band and showed that BHs merging through this channel generate significant eccentricities. These are typically larger than BHs formed through mergers in isolated binary evolution and in SBHB ejected from star clusters (Fragione & Kocsis 2018; Giacobbo & Mapelli 2018; Rodriguez et al. 2018), but comparable to mergers that follow from the GW capture scenario in clusters (Samsing et al. 2018b; Zevin et al. 2019) and galactic nuclei (O’Leary et al. 2009; Gondán et al. 2018; Rasskazov & Kocsis 2019), from hierarchical triples (Antonini et al. 2017), and from BH binaries orbiting intermediate-mass black holes in star clusters (Fragione & Bronberg in prep.). Correlations between mass and eccentricity may distinguish some of these merger channels (Gondán et al. 2018).

To accurately determine the global BH merger rate from quadruples, we would need to quantify the population of massive quadruple stars that lead to a quadruple BH of a given mass, which is currently poorly known. In our study, we have assumed a simple power-law distribution of BH masses in the range $5 M_\odot - 100 M_\odot$. The multiplicity fraction of high-mass main-sequence stars, which may be the progenitors of NSs and BHs, can be as high as $\sim 80\%$ and quadruples are not rare, representing $\sim 20\%-25\%$ of the fraction of stellar objects in triples (Sana 2017). We find that the merger fraction in quadruples can be larger than that for triples, even up to $\sim 5$-10 times larger (see the last column of Tab. 1). Our results thus suggest that dynamically-driven BH and NS mergers in the quadruple scenario can be an important contribution to the events observed by LIGO/VIRGO.

ACKNOWLEDGEMENTS

We thank Dong Lai for useful comments. GF thanks Seppo Mikkola for helpful discussions on the use of the code ARCHAIN. GF is supported by the Foreign Postdoctoral Fellowship Program of the Israel Academy of Sciences and Humanities. GF also acknowledges support from an Arskin postdoctoral fellowship at the Hebrew University of Jerusalem. GF acknowledges hospitality from the Eötvös Loránd University of Budapest. This project has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme under grant agreement No 638435 (GalNUC) and by the Hungarian National Research, Development, and Innovation Office grant NKPFIH-KH-125675 (to BK). Simulations were run on the Astric cluster at the Hebrew University of Jerusalem.
