1 Introduction

Colloids are finely divided particles distributed in a dispersion medium. The diameter of particles ranges from around 10 nm to 10μm [1]. Many of these colloids (viruses, bacteria and protozoan parasites) in surface water pose a risk to public health [2]. Numerous processes are available for the removal of these colloids, which is achieved using an attachment mechanism. Filtration through porous media...
Mechanism of Colloidal Attachment on Textile Fibrous Media

1.1 Filtration theory

Bacteria attachment in porous media as predicted by colloid filtration theory provides a model for determining the physical and chemical factors of particle retention in porous media. Physical controls over bacteria attachment in porous media depend on the geometry of the porous media, as well as bacteria. The number of potential contacts of particles with a surface can be estimated based on a physical mechanism. This, in turn, facilitates the determination of the attachment of particles in porous media, which depends on the chemical forces affecting adhesion and repulsion [12].

Particle removal in a packed bed in a constant state using an attachment mechanism can be described using one-dimensional filtration equation 1 [13].

\[
\frac{dC}{dL} = -\frac{3}{2} \frac{(1-f)}{d_c} \eta C
\]  

where \( C \) is particle concentration (in number of bacterial per unit volume), \( L \) is the thickness of the filter bed, \((1-f)\) is the solid fraction, \( \eta \) is the single collector contact efficiency and \( d_c \) is the collector diameter. Integration of the thickness of the packed bed yield is given in basic filtration equation 2.

\[
F_p = \frac{C}{C_0} = \exp \left( \frac{3}{2} \frac{(1-f)}{d_c} \eta L \right)
\]  

Where \( F_p \) is fractional penetration and this is an indicator of the balance between cell adsorption and desorption.

Physical factors that account for particle collisions with porous media are incorporated into the single collector contact efficiency (\( \eta \)). The single collector contact efficiency of a single media particle or collector (\( \eta \)) is a ratio, i.e. the rate at which particles strike the collector to the rate at which particles flow towards the collector.

Numerous analytical solutions have been used to specify the single collector contact efficiency for filtration through granular media. Primarily transport mechanisms are used to develop the model for the theoretical calculation of single collector contact efficiency.

The Yao model, represented by equations 3–5 describing deep bed filtration for liquid filtration, were proposed by Logan et al. [14]. Single collector contact efficiencies for this model are based on spherical collectors.

\[
\eta_D = 4Pe^{−2/3}
\]  

\[
\eta_I = \frac{3}{2} R^2
\]  

\[
\eta_G = G
\]

Here, \( \eta_D \), \( \eta_I \) and \( \eta_G \) represent theoretical values for the single collector contact efficiency when the sole
transport mechanisms are diffusion, interception, or sedimentation, respectively. Single collector contact efficiency calculated numerically can be approximated by the sum of analytical equation 6. In other words:

\[ \eta_0 = \eta_D + \eta_I + \eta_G \]  

(6)

Single collector contact efficiencies are a dimensionless number and are developed from correlations using equations 7–9.

\[ Pe = \frac{U_0 d_p}{D} \]  

(7)

\[ R = \frac{d_p}{d_c} \]  

(8)

\[ G = \frac{U_p}{U_0} \]  

(9)

Where \( Pe \) is the peclet number, \( R \) and \( G \) are interception and gravitational numbers, \( U_0 \) and \( U_p \) are filter superficial velocity (\( L/T \)) and particle settling velocity (\( L/T \)), \( D \) is the particle diffusivity (\( L^2/T \)), \( d_p \) is the particles diameter and \( d_c \) is the collector diameter. The particle settling velocity is obtained using equation 10.

\[ U_p = \frac{g(p_p - p_f)d_p^2}{18\mu \vartheta_f} \]  

(10)

\( \mu \) and \( \vartheta \), dynamic and kinematic viscosity (\( ML^{-1}T^{-1} \)) of fluid \( g \) is the gravitational constant (\( L/T \)), where \( p_p \) and \( p_f \) the particle and fluid density (\( ML^{-3} \)). The particle diffusivity is obtained using the Stokes-Einstein equation (equation 11).

\[ D = \frac{kT}{3\pi\mu d_p} \]  

(11)

where \( k \) (\( ML^2T^{-2}K^{-1} \)) is Boltzmann’s constant and \( T \) (K) is the absolute temperature. The quantitative assessment of bacterial attachment to a collector surface is carried out by determining the collision efficiency (attachment) factor (\( \alpha \)), and is often expressed as the ratio of experimental single collector efficiency (\( \eta \)), calculated using equation 2, to the predicted single collector efficiency (\( \eta_0 \)), calculated using equation 6, or the possibility that a collision in an attachment, which is obtained using equation 12.

\[ \alpha = \frac{\eta}{\eta_0} \]  

(12)

2. Physicochemical factors of textile fibrous media affecting the removal of colloidal particles

2.1 Fibre size/diameter

In textile porous media, the attachment of colloids on the surface of a fibre is influenced by the fibre diameter. It has been reported that a lower fibre diameter will result in the higher removal efficiency of colloids due to the high specific surface area and good interconnectivity of pores [15]. The mean pore size of a fibrous media is highly dependent on the fibre diameter [16]. Eichhorn and Sampson used a theoretical model to demonstrate that the fibre diameter plays an important role in controlling the pore size of an electrospun nanofibrous network used for water filtration [17]. Zhou et al. [18] studied the removal of colloidal particles in cellulose acetate nanofibers membranes at different fibre diameters. They found that membranes with a lower fibre diameter had a higher removal efficiency than membranes with a higher fibre diameter. Desai et al. [19] studied the bacteria removal efficiency of nanofibers filter media by varying the diameter of the fibre. They reported that an increase in fibre diameter resulted in a decrease in filtration efficiency. It has been reported that the fibre diameter in textile filter media plays an important role in improving filtration efficiency.

2.2 Fibre shape/cross section

Many studies have been carried out on the effect of the shape of the fibre in textile media on colloidal removal in the filtration process. A higher projected surface area resulting from a different cross-section facilitates the probability of capturing colloids particles. Recently, hollow nanofibrous membranes have emerged as substrates for use in liquid filtration [20]. Wang et al. [21] found that hollow fibre membranes have excellent intrinsic separation properties due to their highly porous and narrow pore size distribution, which leads to high filtration efficiency. Fibre cross-section could also be considered an important factor in colloidal filtration in textile filter media.

2.3 Fibre media thickness

The thickness of the media also affects the removal efficiency of a filter. Kaur et al. [22] suggested that if a fibrous media is used to separate sub-microns
particles, a thicker fibrous layer is required to reduce the overall average pore size of the media. A higher media thickness is associated with increased colloidal removal due to the overlapping of the fibres in the media, resulting in fine sized pores, which facilitates the trapping of particles [18]. It has also been reported that the removal of clay particles increases with an increase in the thickness of the polypropylene fibrous barrier. It was claimed that a thicker barrier should provide more chances for the interception of clay particles [23–25].

2.4 Fibre hydrophobicity
The hydrophobicity of textile fibres is considered an important chemical factor that affects colloidal removal in textile fibrous media. Most colloidal particles are hydrophobic in nature. Hydrophobic interaction plays an important role in the efficient removal of colloidal particles [26]. The kinetics of the capture of colloidal particles is also determined by the magnitude of the hydrophobic interaction between particles and collectors. Hydrophobic interaction increases with an increase in the hydrophobicity of the filter media. The hydrophobicity of the media is characterised in terms of contact angle value [11]. Arnold et al. [27] reported that hydrophobicity is directly proportional to the contact angle of water with its surface and inversely proportional to the work of adhesion. Fletcher et al. [28] found a strong positive correlation between the number of bacteria attached to the surface and the hydrophobic nature of polymers, as determined by the contact angle. It is evident in Figure 1 that an increase in the contact angle results in increased bacteria attachment. Pringle et al. [29] calculated a lower work of adhesion for nylon (98 mJ/m²) than for glass (146 mJ/m²). In an experiment with two pseudomonas species, it was observed that the attachment of these cells was higher to the nylon fibres than to the borosilicate glass surface because of the higher hydrophobicity of the nylon fibre.

2.5 Fibre surface charge
The removal of colloidal particles using relatively wide pore size fibrous media can be influenced not only by sieving parameters (pore size and pore size distribution) but also by the chemical interaction taking place between the colloidal particles and fibrous media [30, 31]. Cookson et al. [32] reported that attachment is brought about by the colloid-media chemical interaction controlled by the surface properties of the respective materials. Surface charge is one of the most important surface properties controlling the effective attachment of colloids on the fibre surface in textile fibrous media. It was reported that a possible mechanism for the removal of smaller-sized colloidal particles could be the electrostatic attraction between the opposite charges of the fibres and the particles, which causes the deposition of particles on the fibre surface [33–35]. The fibre surface charge is characterised in terms of zeta potential. It is measured using a streaming potential method on the surface of the fibres. The surface charges of fibres are the result of the disassociation of fibre surface groups in an aqueous medium. The isoelectric point (IEP) is the pH value corresponding to zero zeta potential and is different from fibre to fibre, depending on the surface properties [36]. Kang et al. [33] studied the adsorption of negatively charged nanoparticles on cationic, surfactant-treated microporous polypropylene filters. They reported that filtration efficiency can be increased from 10% to 90% through this surface modification. This can be attributed to the lowering energy barrier between the particles and filter media. Druet et al. [37] investigated the removal efficiency of heavy metal using positively charged, chitosan-treated polyethylene terephthalate geotextiles. They claimed that the higher positive charge of the media at an acidic pH will result in higher metal removal efficiency. In the desalination process based on textile nanofibers membranes, most membranes are characterised by a negative surface
To quantitatively compare removal efficiency with different fibre orientations under identical solution conditions, the value of collision (attachment) efficiency ($\alpha$) is calculated using equation no. 12, which is used in colloidal filtration theory. It has been reported that a high fibre orientation angle may lead to the exposure of a greater surface area for the striking of bacteria, resulting in high collision efficiency. A higher collision efficiency means higher bacteria attachment, where its maximum value is 1. It is evident from Figure 5 that an increase in fibre orientation results in an increase in collision efficiency.

3.2 Effect of fibre mass on bacteria removal efficiency

In another study conducted by Roy et al [43] on the effect of fibre mass on bacterial attachment, it was determined that removal efficiency increases with an increase in media mass up to a certain level (Figure 6). This is due to the change in single collector removal efficiency as a function of media mass [43]
charge to enhance the removal of dissolved salts [38, 39]. Berg et al. [40] found that the electrostatic repulsion force of negatively charged pesticides on the surface of a negatively charged membrane is expected to enhance the overall removal efficiency. Based on the above literature, it can be concluded that the physicochemical factors of textile fibrous media are identified on the basis of filtration efficiency, which is expressed in terms of the concentration variation of colloidal particles in input and output water. The effect of physicochemical factors on the mechanism of attachment of colloidal particles, primarily bacteria on textile fibrous media, may also be systematically investigated by using colloidal filtration theory.

3 Selected approaches to the application of colloidal filtration theory for textile material

An attempt has been made by a few researchers to use colloidal filtration theory to explain colloidal removal by an attachment mechanism in textile porous media. Dagaonkar et al. [41] used DLVO theory to explore the effect of solution chemistry on colloidal removal in nonwoven polyester filter fabric. They reported that under unfavourable attachment conditions using bivalent salt (CaCl₂), removal efficiency increased from 35% to 62% compared to monovalent salt (NaCl), while the removal efficiency remain constant at around 38% for the ionic strength range of 0 to 100 mM (Figure 2).

3.1 Effect of fibre orientation on bacteria filtration

Roy et al. [42] investigated the attachment of bacteria to fibrous material as a function of fibre orientation to the direction of the liquid flow. Removal trends were explained on the basis of colloidal filtration theory. They reported that by changing fibre orientation from 0° to 90°, bacteria removal efficiency increased from 30% to 54.54%, suggesting that the attachment of bacteria on the media surface depends on fibre orientation (Figure 3).

It is evident from Figure 4 that single collector efficiency increases from $1.33 \times 10^{-2}$ to $1.39 \times 10^{-2}$ by changing fibre orientation from 0° to 90°. This is due to a decrement in the approach velocity of the filtration system from $3.09 \times 10^{-3}$ to $2.01 \times 10^{-3}$ m/s. Enhanced single collector contact efficiency by increasing fibre orientation has therefore been attributed to a change in the approach velocity of water in the filtration system. A potential explanation is that a high fibre orientation angle may lead to the exposure of a greater surface area for the striking of bacteria, resulting in high collector contact efficiency.
contact efficiency and attachment/collision efficiency, as observed from experimental data regarding removal efficiency.

It is evident from Figure 7 that changing the media mass increases and then decreases collision efficiency ($\alpha$).

### 3.3 Effect of different fibrous material on bacterial attachment

Many researches have studied the effect of different media material on bacterial attachment in textile fibrous media. Roy et al. [44] reported that nylon fibrous media demonstrates a higher removal efficiency than polyester fibrous media for the same solution chemistry (Figure 8). The bacteria removal efficiency of nylon and polyester fibrous filter media are explained based on colloidal filtration theory.

The removal and attachment of bacteria on a fibrous surface thus increases with an increase in ionic strength, which can be attributed to a change in collision efficiency. It is evident from Figure 9 that the change in collision efficiency is higher for nylon than for polyester, resulting in a higher removal efficiency by nylon fibrous media.

### 4 Conclusion

The reported study demonstrated that the fibre orientation of the filter media may play an important role in bacterial attachment. Bacteria attachment and removal efficiency increase with an increase in the fibre orientation angle. According to colloidal filtration theory, this is possible due to a change in the collision (attachment) efficiency of the fibrous media. Bacteria attachment and removal efficiency increase with an increase in media mass up to a certain level. It is also evident from reported studies that media materials play an important role in bacterial attachment in a fibrous packed bed.

The higher bacteria removal efficiency of nylon fibrous media than polyester fibrous media is due to the higher collision efficiency of nylon fibre (0.24 to 0.46) than polyester fibre (0.23 to 0.42) at the ionic strength range of 1mM to 150 mM.

Hence, the concept of dimensionless $\alpha$ (attachment efficiency) or $\eta$ (single collector contact efficiency) of a granular media filter can be extended to textile filter media for the purpose of explaining the mechanism of attachment of colloids (bacteria) on textile fibrous media.
