Edited by Jeffrey Pessin

The discovery that oxidized vitamin C, dehydroascorbate (DHA), can induce oxidative stress and cell death in cancer cells has rekindled interest in the use of high dose vitamin C (VC) as a cancer therapy. However, high dose VC has shown limited efficacy in clinical trials, possibly due to the decreased bioavailability of oral VC. Because human erythrocytes express high levels of Glut1, take up DHA, and reduce it to VC, we tested how erythrocytes might impact high dose VC therapies. Cancer cells are protected from VC-mediated cell death when co-cultured with physiologically relevant numbers of erythrocytes. Pharmacological doses of VC induce oxidative stress, GSH depletion, and increased glucose flux through the oxidative pentose phosphate pathway (PPP) in erythrocytes. Incubation of erythrocytes with VC induced hemolysis, which was exacerbated in erythrocytes from glucose-6-phosphate dehydrogenase (G6PD) patients and rescued by antioxidants. Thus, erythrocytes protect cancer cells from VC-induced oxidative stress and undergo hemolysis in vitro, despite activation of the PPP. These results have implications on the use of high dose VC in ongoing clinical trials and highlight the importance of the PPP in the response to oxidative stress.

Consistent with its function as a potent reducing agent essential for numerous biological reactions, VC2 can be readily oxidized to dehydroascorbate (DHA) in aqueous solution. DHA is transported intracellularly by Glut1 (solute carrier family 2, facilitated glucose transporter member 1) (1), after which it is recycled to reduced VC at the expense of cellular antioxidants, such as GSH (2, 3). This paradoxical role for VC as a source of oxidative stress has been found to be selectively toxic to some cancer cells, particularly to those overexpressing Glut1 (4, 5). Although the benefits of VC supplementation as a cancer therapy have been inconsistent (6), higher doses of intravenous VC have shown more promise, and several clinical trials are ongoing (7).

Like many cancer cells, human erythrocytes (RBCs) express very high levels of Glut1. The abundance of the Glut1 transporter in erythrocyte membrane allows RBCs to mediate the transport of glucose and DHA at rates that far exceed their capacity to utilize it (3). There is substantial evidence that erythrocytes participate in VC recycling in vivo (8, 9). In addition, erythrocytes have also been found to protect both tissues and cells from H2O2-mediated damage through their high capacity redox systems (10). We hypothesized that erythrocytes might protect cancer cells from VC-mediated toxicity through similar mechanisms. Indeed, we find that physiologically relevant numbers of erythrocytes protected HCT116, A375, and SK-MEL-28 cells from VC-mediated toxicity. Erythrocytes incubated with VC showed higher levels of oxidative stress and shifted glucose metabolism toward the oxidative pentose phosphate pathway (PPP), which produces NADPH for ROS mitigation. Finally, we find that VC induced hemolysis of erythrocytes, which was exacerbated by chemical or genetic inhibition of glucose-6-phosphate dehydrogenase (G6PD) and rescued by incubation with β-mercaptoethanol. This study broadens our current understanding of VC metabolism by erythrocytes and has implications for the use and monitoring of VC in the clinical setting.

Results

Erythrocytes Protect Cancer Cells from VC- and H2O2-induced Cell Death—The selective toxicity of VC to Kras (proto-oncogene v-Raf murine sarcoma viral oncogene homolog B) and Braf (proto-oncogene v-Raf murine sarcoma viral oncogene homolog B) mutant colorectal cancer cells is due, in part, to the high expression levels of Glut1 and preferential uptake of oxidized DHA by the facilitative glucose transporter (5). Consistent with their very high expression of Glut1, erythrocytes have also been shown to transport DHA efficiently (11). We compared the kinetics of DHA uptake by erythrocytes and HCT116 at physiological concentrations of glucose and found

2 The abbreviations used are: VC, vitamin C; DCFDA, 2′,7′-dichlorofluorescin diacetate; DHA, dehydroascorbate; DHEA, dehydroepiandrosterone; PPP, pentose phosphate pathway; G6PD, glucose-6-phosphate dehydrogenase; ROS, reactive oxygen species; MITT, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide; β-ME, β-mercaptoethanol; MTBlFSA, N-tet-butylidimethylsilyl-N-methyltrifluoroacetamide; AA, ascorbic acid.
that erythrocytes accumulated intracellular VC much more rapidly than HCT116 cells (Fig. 1A). Consistent with previous studies on the accumulation of ascorbate in erythrocytes (8), we found that accumulation of VC by RBCs peaked rapidly (~1 min) and decreased slightly over time consistent with the slow release of recycled ascorbate back into the medium. In contrast, the kinetics of DHA uptake by HCT116 cells was delayed and increased slowly over 30 min. The level of rapid uptake and reduction of DHA by erythrocytes is consistent with the undetectable levels of DHA in healthy human serum (12).

Given the rapid kinetics of DHA uptake by erythrocytes, we hypothesized that RBCs might protect cancer cells from VC-mediated toxicity. First, we determined the sensitivities of HCT116 and two BrafV600E mutant melanoma cell lines to VC. Although HCT116 cells were the most sensitive to VC, both BRAF mutant melanoma cell lines were also sensitive to VC-induced cell death at physiological glucose concentrations (Fig. 1B). The intravenous administration of high dose ascorbate has the ability to increase serum ascorbate to >25 mM (7). Thus, all three mutant cells showed sensitivity to VC at pharmacologically relevant doses. Next, these cancer cells were co-cultured with RBCs and then treated with VC. The addition of as few as 10,000 RBCs significantly protected HCT116, A375, and SK-MEL-28 cells from VC-induced toxicity (Fig. 1, C–E). Higher numbers of erythrocytes offered near complete protection of all three cancer cell lines from VC-mediated toxicity. These striking in vitro findings suggest that circulating erythrocytes might exert modifying effects on VC toxicity in the in vivo setting.

The protective effects of RBCs against oxidative stress were not limited to VC. Consistent with reports that RBCs can protect tissues from hydrogen peroxide (H2O2)-induced tissue damage (10), we found that RBCs could protect cancer cells from H2O2-mediated cell death. After first determining the sensitivity of each of the cell lines to H2O2, we also found that as few as 10,000 RBCs could also protect cancer cells from H2O2 toxicity (data not shown). Moreover, the addition of both VC and H2O2 resulted in a synergistic toxicity to the cancer cell lines. Co-culture with erythrocytes provided protection against this synergistic oxidative stress (data not shown).

**Metabolomic Flux Analysis of RBCs Treated with VC—** Despite the high redox capacity of erythrocytes, the uptake and recycling of large amounts of DHA might present an oxidative burden to erythrocytes. To test this, erythrocytes were incubated with the ROS-sensitive dye, 2',7'-dichlorofluorescein diacetate (DCFDA). We found that VC increased the intracellular ROS of erythrocytes in a dose-dependent manner. The amount of oxidative stress induced by VC was comparable with similar concentrations of H2O2 (Fig. 2A). Consistent with the function of GSH as the principal cellular antioxidant responsible for the recycling of DHA by erythrocytes (8), we found that erythrocyte GSH levels decreased significantly upon incubation with VC (Fig. 2B).

The regeneration of GSH from GSSG requires NADPH and GSH reductase. Keratinocytes, fibroblasts, and cancer cells can respond rapidly to oxidative stress by routing glucose flux through the oxidative PPP to generate NADPH (13, 14). Because erythrocytes lack organelles to mount a transcriptional response to oxidative stress, the reduction of NADP+ to NADPH might constitute an especially important facet of the response against RBC oxidative stress. DHA has previously been shown to stimulate oxidation of glucose through the pentose phosphate pathway (9). To quantitate the impact of oxidative stress on glucose flux in RBCs, we used [1,2-13C]glucose to monitor the labeling of glucose-derived metabolites. In this labeling scheme, m+1-labeled metabolites from the lower half of glycolysis (i.e. dihydroxyacetone phosphate, phosphoenolpyruvate, and pyruvate) arise from flux through the oxidative PPP and m+2-labeled metabolites, from glycolysis (Fig. 2C). Importantly, these measurements underestimate total flux through the oxidative PPP as they report only carbons flowing back into the pools of glycolytic intermediates as opposed to supplying ribose-phosphate pools for nucleotide biosynthesis and other branch pathways. In unperturbed erythrocytes, ~4–8% of lower glycolytic intermediates were labeled as m+1. After treatment with VC, the fractional abundance of m+1-labeled products increased significantly, as much as 3-fold for some metabolites (Fig. 2D, top row; supplemental data). Similar changes were observed in H2O2-treated cells. Analysis of other labeled isotopologues revealed significant decreases in the levels of m+2-labeled isotopologues consistent with decreases of up to 20% in the glycolytic pathway after VC treatment (Fig. 2D, bottom row; supplemental data). Interestingly, changes in glucose flux were actually less pronounced in RBCs treated with 1.0 mM VC or 0.1 mM H2O2 than those treated with 0.2 mM VC. High levels of oxidative stress can overwhelm the antioxidant systems of RBCs and compromise RBC membrane integrity and metabolism (15). Thus, we speculate that high levels of oxidant stress may irreparably damage some RBCs and render them metabolically inactive.

**Hemolysis in Erythrocytes Treated with VC—** Incubation of RBCs with VC results in an induction of oxidative stress, depletion of GSH, and increased flux through the PPP. These findings are consistent with the key role of PPP in producing NADPH for RBCs, and suggest that inhibition of the PPP could damage VC-treated RBCs. Although several cases of VC-induced hemolysis have been reported in the literature (16–18), the mechanism of this hemolysis has not been experimentally verified. Importantly, all patients reported to have significant VC-induced hemolysis were found to possess a genetic deficiency of G6PD, a key upstream enzyme of the PPP. First, we tested whether VC might induce hemolysis in normal erythrocytes in vitro. Indeed, we found that pharmacological concentrations of VC induced significant hemolysis as measured by both hemoglobin release and decreased RBC number, with complete hemolysis noted at 1.6 mM VC (Fig. 3A). At lower concentrations of VC, hemolysis was more striking at later time points, likely reflecting the depletion of glucose from the incubation medium (Fig. 3B). Consistent with an important role for the PPP in maintaining RBC redox, dehydroepiandrosterone (DHEA), a PPP inhibitor, significantly exacerbated VC-induced RBC hemolysis under all conditions (Fig. 3, A and B). Moreover, erythrocytes from a G6PD patient showed increased oxidative stress both at baseline and also in response to VC and H2O2 treatments (Fig. 3C). G6PD erythrocytes were also significantly more susceptible to VC-induced hemolysis (Fig. 3D). The incu-
FIGURE 1. Erythrocytes protect cancer cells from VC and H$_2$O$_2$ toxicity. A, $[^{14C}]$DHA uptake assay demonstrates that RBCs accumulate DHA more rapidly than HCT116 cells. B, HCT116 and BRAF mutant melanoma cells (A375 and SK-MEL-28) show a dose-dependent toxicity to VC-mediated toxicity as assessed by MTT. C, photomicrographs of A375 cells reveal that VC treatment (0.6 mM for 24 h) caused cytotoxicity. Co-culture with RBCs (indicated by arrows) rescues cell viability. D, the co-culture of RBCs with HCT116, A375, and SK-MEL-28 cancer cells protects them from VC-induced toxicity as assessed by the MTT assay. An equal number of cells cultured without VC or RBCs was used as the reference (100%) to calculate relative survival ($n = 3$, error bars = S.D.; analysis of variance with Dunnett’s correction; *, $p \leq 0.05$, **, $p \leq 0.01$, ***, $p \leq 0.001$, ****, $p \leq 0.0001$). E, the co-culture of RBCs with HCT116, A375, and SK-MEL-28 protects them from VC-induced toxicity as assessed by cell number.

bation of normal RBCs with β-mercaptoethanol (β-ME), an antioxidant, partially rescued RBCs from both VC-induced oxidative stress (Fig. 3E) and hemolysis (Fig. 3F).

Discussion

Our findings that erythrocytes can protect cancer cells from VC-induced oxidative stress extend previous studies, suggesting an antioxidant role for erythrocytes. Although most clinical trials involving high dose VC include G6PD deficiency as an exclusion criterion, we suggest that all patients at risk of hemolysis be excluded from such trials. Consistent with this suggestion, a recent randomized, double-blind, placebo-controlled trial found that oral supplementation of VC significantly worsened hemolytic markers in sickle cell anemia and β-thalassemia patients, contrary to their expectations (19). Although the presence of sufficient serum glucose might mitigate hemolysis in...
ongoing high dose VC trials, low levels of hemolysis might be detectable even in otherwise healthy patients. To test this possibility, clinical monitoring of hemolytic parameters could be considered in future or ongoing clinical trials. Moreover, our studies suggest that VC alone may have limited utility in blood storage, where it has been tested extensively (20, 21). Rather, preservation of erythrocytes in solutions with glucose and alternative anti-oxidants might better prevent RBC oxidative stress and hemolysis and promote longer term erythrocyte stability during storage.

Our results also highlight the importance of glucose flux through the oxidative PPP as a critical component in the response to oxidative stress. Although many studies have focused on glucose’s roles as an energy source and biosynthetic intermediate, more recent studies have begun to probe the role of glucose flux through the PPP in the response to oxidative stress (13, 22). We speculate that the dependence of RBCs on the PPP in the response to oxidative stress might help explain why they have evolved to express extraordinarily high levels of the Glut1 transporter. It will be interesting to test whether other cell types that express high levels of glucose transporters show a similar dependence on glucose in the response to oxidative stress.

**Experimental Procedures**

**Cell Lines, Cell Culture, RBC Co-culture, and Treatments—**A375 and SK-MEL-28 cell lines were cultured in DMEM (Gibco 11965) supplemented with 10% FBS and 1% penicillin-streptomycin. HCT116 cells were cultured in the same medium with 5% FBS. For VC and/or H2O2 treatment, cells were seeded at a density of 5000 cells/well in a 96-well plate in 100 μl of DMEM (Gibco A14430) supplemented with 5 mM glucose and 10% heat-inactivated FBS at 37 °C in 5% CO2. ROS levels in RBCs were quantified by BD FACSCalibur flow cytometer using DCFDA staining. For H2O2 treatment, 5 μM DCFDA was first added to the cells, followed quickly by the addition of different doses of H2O2; samples were collected after 30 min. For VC treatment, VC was first added to the RBCs, and after a 2-h incubation, 5 μM DCFDA was added, and then cells were collected after 30 min. For cancer cell ROS measurements, cells were seeded at a density of 1 x 10^6 cells/well in a 12-well plate in the same medium as described for VC and H2O2 treatment. After 24 h, 1 x 10^6 RBCs were added to the indicated wells. Next, H2O2 was added to the cells, followed quickly by the addition of DCFDA. Cancer cells were collected after 30 min for FACS analysis. For intracellular GSH measurement, RBCs were treated with VC or H2O2, for 120 or 30 min, respectively, quickly collected on ice, gently washed once with ice-cold culture medium, and then lysed in 200 μl of GSH assay buffer. GSH was measured using the GSH Colorimetric Assay Kit (BioVision) following the manufacturer’s instructions.

**(1,2-13C)Glucose Flux Analysis—**2 x 10^7 RBCs were added to 5 ml of medium supplemented with 5 mM [1,2-13C]glucose or unlabeled glucose and 10% dialyzed FBS with or without vitamin C or H2O2. RBCs were carefully dispersed after addition to the medium. After 6 h, cells were collected by centrifugation at 1500 rpm for 10 min at 4 °C. The medium was aspirated, and the cells were frozen in liquid nitrogen, lysed with three freeze-thaw cycles in 1 ml of 50% methanol (MeOH), and then centrifuged to remove protein debris. The lysates were dried, methoximated, and derivatized with 10 mg/ml methoxymine (Fisher PI-45950) at 70 °C for 10 min followed by 105 μl of MTBSTFA (Sigma 394882) at 70 °C for 1 h. After derivatization, 1 μl of the sample was injected onto an Agilent 6970 gas chromatograph networked to an Agilent 5973 mass selective detector. The abundance of the following ions was monitored: m/z 484–487 for dihydroxyacetone phosphate, m/z 261–264 for lactate, m/z 453–456 for phosphoenolpyruvate, and m/z 174–177 for pyruvate.

**DHA Uptake Assay—**Transport measurements were performed as described previously with modifications (11, 23). Ascorbic acid, l-[1-14C] (ARC 1569) was purchased from American Radiolabeled Chemicals. Labeled ascorbic acid purchased from PerkinElmer did not perform as reported in control uptake assays. HCT116 cells were seeded in triplicate in 12-well plates (250,000 cells/well) for 18–24 h, washed twice with PBS, and incubated with serum-free DMEM containing 0.1% BSA for 2 h. Cells were then washed and incubated in
Ringer's solution (126 mM NaCl, 5 mM KCl, 1 mM MgSO₄, 32 mM HEPES, 2.5 mM glucose, 1 mM CaCl₂, 0.1% BSA, pH 6.0). Ascorbate oxidase (10 units/ml) was used to convert [14C]AA to [14C]DHA, and transport was initiated by the addition of 0.5 μCi of [14C]AA and 100 μM cold AA to each well. Uptake assays were performed for 0, 1, 3, 9, and 27 min at room temperature. Transport was terminated by the removal of uptake solution followed by four washes with ice-cold stop solution containing 100 μM phloretin and 10 μM cytochalasin B in PBS. For DHA uptake in RBCs, 20 μl of erythrocyte suspension containing 2.5 × 10⁹ cells in Ringer's solution was used for each reaction. Uptake was initiated by adding 100 μl of Ringer solution containing 0.5 μCi of 100 μM cold AA to each sample for the indicated time points. Transport was terminated by the addition of ice-cold stop solution. Cells were centrifuged at 16,000 × g for 1 min followed by three additional washes. Both HCT116 and mH9262
