Abstract: This work presents a new wave energy converter power take off (PTO) system that combines two recent developments in drive train technology, the consequent pole linear vernier hybrid permanent magnet machine and the linear magnetic gear. The combined system is fully realised in three-dimensional finite element method and compared to a similar direct drive machine. While the resulting system is lighter, reducing the active material mass by 30%, and more efficient, the system requires larger amounts of high cost permanent magnet material and increased PTO complexity. It is summarised that while such a system could be recommended in certain conditions, it is not viable for general application.

1 Introduction

With an estimated 17 PWh/year\textsuperscript{1} wave energy has enormous potential as both an alternative energy resource and a commercial opportunity. The technology faces some issues however which have, to date limited its development. Key among these issues are the high operation and maintenance (O&M) costs and low speed, low frequency nature of the resource itself. While a variety of devices are in development there is currently no industrial scale ready device. This can largely be attributed to the extreme environments that wave energy converters (WECs) operate in. Potential wave energy sites are usually in remote locations with fundamentally harsh conditions resulting in prohibitive O&M costs. A key issue further exacerbating the O&M costs is the natural low frequency of the resource itself. In order to generate electrical energy efficiently at grid frequency WEC developers have turned to intermediary speed enhancement systems such as mechanical gears or hydraulics. Mechanical gears, however, are a leading cause of downtime in offshore wind\textsuperscript{2} and hydraulic systems increase the complexity of the power take off (PTO) and often have efficiency issues. Alternatively, the use of direct drive machines with fully rated converters has been suggested, removing the O&M issues of mechanical gears\textsuperscript{3}. This requires physically large, expensive machines due to the required high pole number and studies have found that there is similar downtime resulting from the fully rated converter\textsuperscript{4}.

Electrical machines are sized on their value of torque or force. Introducing a gearbox to increase speed and reduce torque is commonly used in rotary electric drives. Previous work in linear machines has shown that that amplitude amplification can be advantageous for PTO in wave energy, where the increased translator mass required to accommodate the increased oscillation amplitude can be offset by reducing the axial length of the machine due to the reduced force requirement\textsuperscript{5}. Introducing amplitude amplification in the form of a linear gear box is therefore a method of reducing the burden on the electrical machine, albeit at the expense of an increased oscillation amplitude. This concept is only advantageous if the combined mass and cost of the gearbox and the smaller electrical machine is significantly below that of the original direct driven machine.

This paper proposes an alternative solution that combines two recent developments in drive train technology, the magnetic gear (MG)\textsuperscript{6} and the consequent pole linear vernier hybrid permanent magnet (CPLVHPM) machine\textsuperscript{7}. Both technologies will be discussed in relation to their topologies and potential benefits in wave energy applications. Then a case study is presented where the linear generator will be scaled to deliver rated power for a direct drive device. A linear magnetic gear (LMG) (Fig. 1) is then designed for integration with the generator. This requires the linear machine to deliver a lower force at increased frequency, hence requiring a smaller active area (smaller stator) but over a larger displacement (longer translator). Mass and efficiency savings, calculated using an three-dimensional (3D) finite element analysis model, are presented to assess the merit of using MGs in a linear system.

2 CPLVHPM machines

The CPLVHPM machine\textsuperscript{7} is a developed version of the vernier hybrid machine (VHM) with an improved magnet consumption\textsuperscript{8}. This machine comprises of double-sided stators with two identical E-shapes facing each other in which both permanent magnets (PMs) and windings are located in the same part of the machine, the E-shaped stator. The long iron laminated translator with salient teeth is sandwiched between the stator sides as shown in Fig. 2. The translator possesses a simple pure iron rigid structure which is inherently low cost to produce a thrust force. This class of machine has the same basic structure as the baseline VHM, except the substitution of PMs with tapered ferromagnetic poles, the consequent poles. All remaining magnets have the same polarity, while the ferromagnetic poles take over the role of the missing poles. Hence, the number of pole pairs of the PM for the baseline VHM and consequent pole machine are equal. Fig. 1 confirms that smaller pole to pole flux leakage is produced by the consequent pole machine compared to its VHM counterpart.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig1.png}
\caption{Effect of consequent poles on leakage flux}
\end{figure}
In other words, the flux linkage of the consequent pole machine is higher than that of the baseline machine. The effect of employing tapered consequent pole on the back electromotive force (EMF) and cogging force characteristics has been investigated in [1]. The salient feature of using this configuration is the saving of 50% of the PM materials, especially in long stroke applications.

The operation principle of the CPLVHPM is based on the magnetic gearing effect where the translator teeth are utilised to modulate the stationary magnetic field produced by PMs to the high-speed traveling magnetic field in the air gap. When the translator at its initial position and its salient teeth are fully aligned with the magnets belong to the phase A, the flux linkage in the coils reaches its maximum negative value, while the back EMF is zero. As the translator moves 90° electrical the flux linkage drops steadily to zero, at which point the back EMF achieves its maximum positive value. Then the polarity is reversed in the next alignment position, corresponding to a 1/2 translator pitch of movement. Therefore, a small translator displacement can produce a high rate change in the flux linkage, and enhancing thrust density and making the machine suitable for low speed direct drive applications.

3 Magnetic gears overview

MG's operate through the contactless transfer of torque between rotors in a rotary topology, or translators in a linear system, introducing a speed step change while experiencing virtually no wear and have greatly reduced lubrication requirements reducing maintenance frequency. Additionally, MGs have reduced acoustics and each rotor can be hermetically sealed from the other, allowing for greater options regarding marinisation. A key design constraint which should be mentioned is the high force translator are placed in the airgap between the inner and outer magnetic pole element fixed the gear ratio, and making the machine suitable for low speed direct drive applications.

The type of MG developed in this work is a ferromagnetic pole field modulated, LMG. While the concentric MG was first patented in 1968 it was Atallah and Howe’s work from 2001 which established its operating principal and high torque capabilities [6]. Initially developing the concentric rotary design, the linear model’s performance was also demonstrated in [9]. The LMG has three main components: a low speed ferromagnetic pole translator, and high-speed PM pole translator and fixed outer magnetic poles.

The ferromagnetic pole pieces (FMPs) forming the low speed, high force translator are placed in the airgap between the inner and outer PM pole elements as shown in Fig. 3. The FMPs modulate the magnetic field in the air gap such that each translator sees the corresponding pole number on the opposite translator allowing for pole alignment and the gearing effect to be established. With the outer magnetic pole element fixed the gear ratio, \( G_s \), is calculated as

\[
G_s = p_l / p_h = (n_h - n_l) / n_l = -v_h / v_l
\]

where \( p_h \) and \( p_l \) are the pole pair numbers on the high and low speed translators, respectively, \( v_h \) and \( v_l \) are the velocities of the high and low speed translators, respectively, and \( n_l \) is the number of FMP pieces which is determined by

\[
n_l = p_h + p_l
\]

Beyond these fundamental design values there are numerous parameters that will effect the performance of a design, the coupling effects of which have been explored in [11] and make designing an ideal system non-trivial.

A key design constraint which should be mentioned is the torque harmonics that occur due to pole number. The harmonic variation can be quantified using (3) which defines a cogging factor \( f_c \) where

\[
f_c = (2pn_h) / (LCM(p_h, n_l))
\]

where \( p \) is the pole pair number on either rotor and LCM is the least common multiple of these two values. For low harmonics this number should be as close to unity as possible [12].

4 Case study

This paper proposes combining a CPLCHPM machine with a LMG which would operate as a PTO for a heaving buoy type WEC. The proposed system block diagram layout can be seen in Fig. 4. In order to see the advantages of a combined system the linear machine was first designed as a scaled direct drive PTO. The key design parameters were a max thrust force of 740 N and a speed of 1.2 m/s resulting in a peak power rating of 888 W. An LMG with a ratio of 3:1 was then designed with objective peak force of 740N. The MG must be designed for a given stroke amplitude as this will greatly affect the size and cost of the device. As the high-speed translator will move increased distances determined by the gear ratio, having a large ratio might result in a prohibitively large system. In this case study a stroke amplitude of 5 cm was chosen for the low speed translator. The high-speed translator will then move 16.5 cm at maximum amplitude and the fixed outer rotor magnetic poles will have to be at least this height in order to ensure continual magnetic field connection between translators.

4.1 Magnetic gear design

The MG was designed through a similar process to that detailed in [13] which involved initial rapid designing and optimising using 2D FEMM and then a full 3D analysis using Infolytica’s MagNet to verify results. When the 3D analysis was performed with the same parameters as the 2D model, there was a reduction of ~11% in the peak forces. To address this difference, the 3D model was adapted such that the correct target force was achieved in order to assess the extra material required for a completed design. The key values and results are shown in Table 1 with the force curves of the initial 2D model, 3D model of the same design and the 3D model of the adapted design shown in Figs. 5 and 6. The models were statically solved at 25 points in order to determine the full force range of...
each model. The primary force effecting parameters are the magnetic pole thickness, air gap radius and the height of the inner high-speed translator. The air gap radius is defined as the distance from the centre axis to the start of the inner air gap while the inner translators height determines the active magnetic area. These parameters are shown in Fig. 7.

5 Combined system discussion

The key results of the combined system for the CPLVHPM machine are shown in Table 2 where the machines parameters are shown before and after the combination with the LMG. With the addition of the LMG the linear machine's total mass is reduced by almost 63% with the key high cost PM material reduced by 66%. Though there is an increase in iron and eddy current losses in the PMs, due to the increase in frequency, the dominant copper losses are reduced by approximately one-third. The resulting machine is then more efficient while being lighter, materially cheaper and more compact. When designing a MG the differences that occur between 2D and 3D models are non-trivial and highlights the importance of full 3D analysis. Such differences have been observed in previous works [14, 15] and given the small dimensions of the gear, 3D effects can have a fairly substantial influence on the magnetic field and resulting forces. Further analysis is ongoing to determine whether the difference in results is reduced when the device is scaled for larger applications. In order to present the most realistic results the full 3D finite element method (3D FEM) model was considered to be the more accurate as it accounts for these 3D effects. The final design resulted in a total mass reduction of 30%. The key results of the direct drive and combined system using the 3D results are presented in Figs. 8–10.

These values are for active material only however and auxiliary elements will be required to connect and support the system.

| Table 1 LMG parameter values |
|--------------------------------|
| Parameter | 2D model (from FEMM) | 3D model (from 2D design) | 3D model (from MagNet) |
|----------------|-------------------|-----------------|-------------------|
| inner magnetic pole thickness, mm | 4 | 4 | 4 |
| outer magnetic pole thickness, mm | 2 | 2 | 2 |
| ferromagnetic pole thickness, mm | 5 | 5 | 5 |
| air gap radius, mm | 25 | 25 | 25 |
| inner translator height, mm | 63 | 63 | 69 |
| inner air gap, mm | 1 | 1 | 1 |
| outer air gap, mm | 1 | 1 | 1 |
| outer backiron thickness, mm | 8 | 8 | 8 |
| inner backiron thickness, mm | 8 | 8 | 8 |
| magnetic mass, kg | 0.422 | 0.422 | 0.623 |
| active iron mass, kg | 3.116 | 3.116 | 4.158 |
| total active gear mass, kg | 3.538 | 3.538 | 4.781 |
| peak (high) force, N | 772 | 684 | 784 |
As the CPLVHPM machine has been purposefully designed in order to decrease the high cost PM material, a combined MG system with greater PM requirements will be, in most cases, infeasible. Furthermore, as a main advantage of direct drives is the relative simplicity of the PTO, the addition of a gearing element without substantial advantages in efficiency or cost would result in no net benefit. Despite these issues the proposed system could have applications where the conditions are characterised by low amplitude, low frequency regular waves. This could potentially increase the viability of certain sites for wave energy development.

6 Conclusion

The magnetically geared linear generator presented in this work has potential as a PTO in WEC technology. The resulting model, fully realised in 3D FEM, was lighter than the non-gearred alternative while resulting in a more efficient generator. Despite these advantages such a system will have limited application as the addition of the gear will increase the complexity of the PTO and the larger amount of required PM material reduces the advantage of using the CPLVHPM machine. Further work is planned to investigate whether it is possible to design a more integrated system rather than the basic series setup described in this work. This could potentially increase the viability of a combined system.
