We show that the enhancement of the saturation scale in large nuclei relative to the proton is significantly influenced by the effects of quantum evolution and the impact parameter dependence of dipole cross sections in high energy QCD. We demonstrate that there is a strong \( A \) dependence in diffractive deeply inelastic scattering and discuss its sensitivity to the measurement of the recoil nucleus.

PACS numbers: 24.85.+p, 13.60.Hb

The properties of hadronic and nuclear wave functions at high energies are of great importance in understanding multi-particle production in QCD. Especially intriguing is the possibility that the small Feynman \( x \) components of these wavefunctions demonstrate universal behavior that is insensitive to the details of hadron or nuclear structure in the (large \( x \)) fragmentation region.

The specific nature of universal small \( x \) dynamics in QCD follows from the strong enhancement of gluon bremsstrahlung at small \( x \) leading to a rapid growth of the occupation number of a transverse momentum mode \( k_\perp \) in the hadron or nuclear wavefunction. However, it can maximally be of order \( 1/\alpha_s \) (where \( \alpha_s \) is the QCD coupling constant) because of non-linear multi-parton effects such as recombination and screening which deplete the gluon density at small \( x \) [1]. In particular, the occupation number is maximal for modes with \( k_\perp \lesssim Q_s \), where \( Q_s(x) \), appropriately called the saturation scale, is a scale generated by the multi-parton dynamics. For a probe with transverse resolution \( 1/Q^2 \), this scale is manifest in a universal scaling form of observables as a function of \( Q/Q_s \) in a wide kinematical range in \( x \) and \( Q^2 \).

In addition to the strong \( x \) dependence generated by gluon bremsstrahlung, the saturation scale \( Q_s \) has a strong \( A \) dependence because of the Lorentz contraction, in the probe rest frame, of the nuclear parton density. For large enough \( A \) and small enough \( x \), the saturation scale is larger than \( \Lambda_{QCD} \), the fundamental soft scale of QCD. In this letter, we will discuss the \( A \) and \( x \) dependence of the saturation scale and some of its ramifications for hard diffraction in nuclei.

A saturation scale arises naturally in the Color Glass Condensate (CGC) [2] description of universal properties of hadron and nuclear wavefunctions at small \( x \). The CGC, when applied to Deeply Inelastic Scattering (DIS), results [3 4], at leading order in \( \alpha_s \), in the dipole picture of DIS [5], where the inclusive virtual photon hadron cross section is

\[
\sigma_{\gamma p}^{\gamma p} = \int d^2r_\perp \left[ \Psi_{\perp,T}^{\gamma}(z) \right]^2 \int d^2b_\perp \frac{d\sigma_{\text{dip}}^{\text{p}}}{d^2b_\perp}. \tag{1}
\]

Here \( \left[ \Psi_{\perp,T}^{\gamma}(r_\perp, z, Q) \right]^2 \) represents the probability for a virtual photon to produce a quark–anti-quark pair of size \( r = |r_\perp| \) and \( \frac{d\sigma_{\text{dip}}^{\text{p}}}{d^2b_\perp}(r_\perp, x, b_\perp) \) denotes the dipole cross section for this pair to scatter off the target at an impact parameter \( b_\perp \). The former is well known from QED, while the latter represents the dynamics of QCD scattering at small \( x \). A simple saturation model (known as the GBW model [6]) of the dipole cross section, parametrized as \( \frac{d\sigma_{\text{dip}}^{\text{p}}}{d^2b_\perp} = 2(1 - e^{-r^2 Q^2_s(x)/4}) \) where \( Q_s^2(x) = (x_0/x)^A \text{GeV}^2 \), gives a good qualitative fit to the HERA inclusive cross section data for \( x_0 = 3 \times 10^{-4} \) and \( \lambda = 0.288 \). However, the model does not contain the bremsstrahlung limit of perturbative QCD (pQCD) that applies to small dipoles of size \( r \ll 1/Q_s(x) \).

In the classical effective theory of the CGC, to leading logarithmic accuracy, one can derive the dipole cross section [4] containing the right small \( r \) limit. This dipole cross section can be represented (see however [7])

\[
\frac{d\sigma_{\text{dip}}^{\text{p}}}{d^2b_\perp} = 2 \left[ 1 - \exp \left( -r^2 F(x, r) T_p(b_\perp) \right) \right], \tag{2}
\]

where \( T_p(b_\perp) \) is the impact parameter profile function in the proton, normalized as \( \int d^2b_\perp T_p(b_\perp) = 1 \) and \( F \) is proportional to the DGLAP evolved gluon distribution [8]

\[
F(x, r^2) = \pi^2 \alpha_s \left( \mu_0^2 + 4/r^2 \right) x g(x, \mu_0^2 + 4/r^2) / (2N_c). \tag{3}
\]

The dipole cross section in Eq. (2) was implemented in the impact parameter saturation model (IPsat) [8] where the parameters are fit to reproduce the HERA data on the inclusive structure function \( F_2 \).

In general, the dipole cross section can range from 0 in the \( r \to 0 \) color transparency limit to \( 2 \), the maximal unitarity bound. The saturation scale \( Q_s \) characterizes the qualitative change between these regimes; we shall here define \( Q_s \) as the solution of \( \frac{d\sigma_{\text{dip}}^{\text{p}}}{d^2b_\perp}(x, r^2 = 1/Q^2_s(x, b_\perp)) = 2(1 - e^{-1/4}) \) [4].

The IPsat dipole cross section in Eq. (2) is applicable when leading logarithms in \( Q^2 \) dominate over leading logarithms in \( x \). At very small \( x \), quantum evolution in the CGC [2] describing both the bremsstrahlung limit of linear small \( x \) evolution as well as nonlinear RG
tial dipole cross section is well approximated by \[9\] average of an observable for individual nucleons to nuclei is to introduce the coordinates of the individual models. Between these “classical CGC” and “quantum CGC” models, the data for \(Q^2\) provide excellent fits to a wide range of HERA data. Center: predictions for 12\(F_2^{\mathrm{NMC}}/118F_2^{\mathrm{p}}\) compared to NMC data at \(x = 0.0125\). Right: Likewise for \(Q^2 = 5\) GeV\(^2\) as a function of \(x\).

Evolution at high parton densities, combined with a realistic \(b\)-dependence, is better captured in the bCGC model \([10,11]\). Both the IPsat model and the bCGC model provide excellent fits to a wide range of HERA data for \(x \leq 0.01\) \([11,12]\). We will now discuss the possibility that DIS off nuclei can distinguish respectively between these “classical CGC” and “quantum CGC” motivated models.

A straightforward generalization of the dipole formalism to nuclei is to introduce the coordinates of the individual nucleons \(\{b_{1,i}\}\). One obtains in the IPsat model,

\[
\frac{d\sigma_{\mathrm{dip}}^A}{dx_b} = 2 \left[ 1 - e^{-r^2 F(x,r) \Sigma_{i=1}^A T_p(b_{1,i} - b_{1,i})} \right],
\]

where \(F\) is defined in Eq. \([3]\). The positions of the nucleons \(\{b_{1,i}\}\) are distributed according to the Woods-Saxon distribution \(T_p(b_{1,i})\). We denote the average of an observable \(O\) over \(\{b_{1,i}\}\) by \(\langle O \rangle_N \equiv \int \prod_{i=1}^N d^2b_{1,i}T_p(b_{1,i})O(\{b_{1,i}\})\). The average differential dipole cross section is well approximated by

\[
\langle \frac{d\sigma_{\mathrm{dip}}}{dx_b} \rangle_N \approx 2 \left[ 1 - \left( 1 - \frac{T_A(b_{1,i})}{T_A(b_{1,i})} \right) \sigma_{\mathrm{dip}} \right]^A,
\]

where, for large \(A\), the expression in parenthesis can be replaced by \(\exp \left( -\frac{A T_A(b_{1,i})}{2} \sigma_{\mathrm{dip}} \right)\). All parameters of the model come from either fits of the model to \(eA\)-data or from the Woods-Saxon distributions; no additional parameters are introduced for \(eA\) collisions. The same exercise is repeated for the bCGC model.

In Fig. \([1]\) (left), we compare the prediction of the IPsat and bCGC models with the experimental data \([25]\) on nuclear DIS from the NMC collaboration \([14]\). Figure \([1]\) (right) shows that the \(x\) dependence of shadowing for fixed \(Q^2\) in the IPsat model is very flat. This is because the best fit to \(eA\)-data in DGLAP-based dipole models \([8,9]\) is given by a very weak \(x\)-dependence at the initial scale \(\mu_0^2\). A stronger \(x\)-dependence also for large dipoles, such as in the in the GBW or bCGC models, gives a stronger \(x\)-dependence of shadowing at fixed \(Q^2\). As shown in Fig. \([1]\) (center), both the IPsat and bCGC models predict strong \(Q^2\)-dependence (at fixed \(x\)) for shadowing. It is this latter effect which is primarily responsible for the shadowing effect seen in the NMC data. Precision measurements of \(F_2^A/F_2^p\) would shed more light on the relative importance of \(Q^2\) and \(x\) evolution in this regime.

We now turn to a discussion of the \(A\) and \(x\) dependence of the saturation scale. In a simple GBW type model, inserting a \(\theta\)-function impact parameter dependence into Eq. \([5]\) yields the estimate \(Q_{s,A}^2 \approx A^{1/3} \frac{b_{1,i}^2}{R_A} Q_{s,p}^2 \approx 0.26 A^{1/3} Q_{s,p}^2\) for \(2\pi r_p^2 \approx 20\) mb and \(R_A \approx 1.1 A^{1/3}\) fm. The smallness of \(Q_{s,A}^2/Q_{s,p}^2\), due to the constant factor \(\sim 0.26\) has sometimes been interpreted \([9,13,10]\) as a weak nuclear enhancement of \(Q_s\). We will argue here that detailed considerations of QCD evolution and the \(b\)-dependence of the dipole cross section result in a significantly larger nuclear enhancement of \(Q_s\).

The effect of QCD evolution on \(Q_{s,A}\) in the IPsat nuclear dipole cross section is from the DGLAP-like growth of the gluon distribution. The increase in the gluon density with increasing \(Q^2\) and decreasing (dominant) dipole radius \(r\) causes \(Q_s\) grow even faster as a function of \(A\). This is seen qualitatively for two different nuclei, \(A\) and \(B\) (with \(A > B\)), in a “smooth nucleus” approximation of Eq. \([4]\) whereby \(\sum_{i=1}^A T_p(b_{1,i})\) is replaced by \(AT_A(b_{1,i})\). We obtain

\[
\frac{Q_{s,A}^2}{Q_{s,B}^2} = \frac{A T_A(b_{1,i})}{B T_B(b_{1,i})} \frac{F(x,Q_{s,A}^2)}{F(x,Q_{s,B}^2)} \approx A^{1/3} \frac{F(x,Q_{s,A}^2)}{F(x,Q_{s,B}^2)}. \quad (6)
\]

The scaling violations in \(F\) imply that, as observed in Refs. \([3,17]\), the growth of \(Q_s\) is faster than \(A^{1/3}\). Also, because the increase of \(F\) with \(Q^2\) is faster for smaller \(x\), the \(A\)-dependence of \(Q_s\) is stronger for higher energies. In contrast, the dipole cross section in the bCGC model depends only on the “geometrical scaling” combination \([26]\) \(rQ_s(x)\) without DGLAP scaling violations and therefore does not have this particular nuclear enhancement \([27]\). Precise extraction of the \(A\) dependence of \(Q_s\) will play an important role in distinguishing between “classical” and “quantum” evolution in the CGC.

A careful evaluation shows that because the density profile in a nucleus is more uniform than that of the proton, the saturation scales in nuclei decrease more slowly with \(b\) than in the proton. The dependence of the saturation scale on the impact parameter is plotted in Fig. \([2]\). The saturation scale in gold nuclei at the median impact parameter for the total cross section \(b_{\text{med.}}\) is about 70% of the value at \(b = 0\); in contrast, \(Q_{s,p}^2(b_{\text{med.}})\) is only \(\sim 35\%\) of the value at \(b = 0\).

The \(A\) dependence of the saturation scale for various \(x\) is shown in Fig. \([3]\) for the IPsat model on the left and
We will consider only the IPsat model here. The contribution of hard diffraction off nuclei (see also [20]). For small impact parameters, the matter density in a proton is shown as $A = 1$ and by the arrows on the right. Left: IPsat model. Right: bCGC model.

The difference between “no break up” and “break up” integrated cross sections can be seen in Fig. 5 where we plot, as a function of $A$ for fixed $x$ and $Q^2$, the double ratio $R_{\text{diff}}^A$, defined as the ratio $(\sigma_D^P + \sigma_L^P)/(\sigma_D^x + \sigma_L^x)$ from Eqs. (11) and (5) for a nucleus divided by the same ratio for a proton. For light nuclei ($A < 40$), $R_{\text{diff}}^A < 1$ before going well above unity for large $A$. This is because the inclusive $q\bar{q}$ cross section is dominated by smaller impact parameters than the inclusive cross section; at small impact parameters, the matter density in a proton is larger than in light nuclei. For large nuclei, especially in the “break up” case, the nuclear enhancement of the fraction of diffractive events can be quite significant, up to a 100% enhancement relative to the fraction for a proton.

We thank A. Caldwell, C. Marquet and L. Motyka for very useful discussions. This manuscript has been authorized under Contract No. DE-AC02-98CH10886 with the U.S. Department of Energy.

[24] Our definition is equivalent to the saturation scale in the GBW model for a Gaussian dipole cross section. Note the difference with the convention in Ref. [10].

[25] Data available from the E665 collaboration differ from the NMC data for a similar kinematic range.

[26] See, however Ref. [18] on “pre-asymptotic” violations of geometrical scaling.

[27] Another interesting possibility that running coupling log $x$-evolution results in a depletion of the $A$-dependence of $Q^2$. [10].

[28] The contribution of higher Fock states will be addressed in future work.

[29] A comparison of Eqs. (1) and (8) makes explicit the unitarity limit $\sigma_{\text{dip}}^f(T) \leq \sigma_{\text{dip}}^t/2$, which is saturated by a black disk, $\frac{d\sigma_{\text{dip}}^f(B, \perp)}{d\Omega} = 20(R-b)$, leading to the $t$-distribution $\sim 4|J_1(\sqrt{-t}R)|^2/(-tR^2) \approx 1 + tR^2/4 + O(t^2)$. In contrast, an exponential $t$ distribution $\sim e^{-tB}$ (see e.g. [21]) corresponds to a Gaussian in $b$, where the unitarity limit, saturated by $\frac{d\sigma_{\text{dip}}^f}{d\Omega} = 2e^{-t^2/(2\delta t)}$, is $\sigma_{\text{dip}}^f \perp \leq \sigma_{\text{dip}}^t/4$. Specifying the $b_{\perp}$ dependence of the dipole cross section simultaneously fixes both the normalization $\sigma_0$ of the cross section and the diffractive slope $B = d\ln \sigma^f / dt\mid_{t=0}$. ($\sigma_0/B = 8\pi$ and $\sigma_0/B = 4\pi$ for black disk and Gaussian respectively.)
